other hand, we need to guarantee the completeness of the information set and gather all the necessary information on record to achieve information availability, defined as the ability of the systems responsible for delivering, storing and processing the information to be accessed when needed. Therefore, the precondition for a cost-effective tracking system is to make sure what kind of information should be gathered and shared, and to what extent [8,23,24]. Thomas *et al.* [8], Steele [16], Jansen-Vallers *et al.* [25], Bertrand *et al.* [26], Miller [27], and Verdenius [28] present required data categories in detail, mostly for the food industry. We try to provide some general guidance on how to select the right set of data to a proper level for a certain party in a supply chain.

Business Interest. Different parties in a supply chain may have different interests in the sort of data they want to gather. For example, manufacturers are interested in raw material and production information, while retailers pay more attention to the logistics, retailing, and product quality information. Some data can be collected within its own business, some needs to be retrieved from others. For instance, retailers can collect sales information within their four walls; however, they are also interested in product logistics and quality information, which needs to turn to the logistics providers and product inspection and quarantine departments. The union of all the parties' interested information constitutes the complete data set, requiring the cooperation of the entire supply chain.

Risk Sensitivity/Information Traffic. When the data is accumulating as time goes on, the required database memory will sharply increase. More importantly, the data retrieval speed and efficiency are likely to deteriorate when the database overspreads. If the database memory is limited, two types of data as follows have higher priority to be included in the data set: (i) the vital data whose absence may result in significant loss in profit or reputation, (ii) certain data that is of interest to various parties and is retrieved frequently with high information traffic.

Information Distribution

The circulated information in the supply chain can be stored in the tag or in the back database by linking the information to the tag ID. Depending on different information sharing modes: distributed, centralized [29], or hybrid [8], the data stored in the database could be in the local IT system of each party or in the central database, if there is one. The information in the central database may come from the local IT systems or from other institutes for the integrated statistical data. The consideration of information distribution refers to locating the proper place to store the respective kind of data. Different industry requirement, competition environment, government regulations, and industry specifications have different impacts on the information distribution strategy, which requires intensive understanding of the business context of different industries.

For example, the European Union, United States, and Japan mandate the traceability of the food industry [30–32], such as requiring a manufacturing date be recorded. This piece of information is also frequently retrieved by logistics providers, wholesalers, retailers and end customers. Therefore, it is advisable to store the manufacturing date in the central database. However, the detailed information about the raw material supply will not be accessed so frequently and the supply network is sensitive to the competitors, suggesting that only the authorized partners can access. In this sense, storing the supplier information in the local database is preferred. For example, in the wine industry, the temperature during transportation is critical to wine quality. Temperature sensors embedded in the RFID tags are usually applied in this cold chain management to

monitor the temperature change [33]. It will be more convenient for the logistics providers, the wine agents, the retailers, and even the end consumers to update or check the temperature information in the RFID tags, rather than linking to the back database for operation. Generalized from the industry observations, guidance for information distribution is summarized in Table 3.

Standardization

To ensure the tracking system works efficiently among all the involved parties with different operations, coding methods, and local IT systems, it is important to make sure everyone speaks the same language and holds the same understanding. We list several key aspects regarding standardization as follows.

Standardize the Data Semantic and Format.

For every single piece of information in the supply chain, different existing systems may have different explanations and formats. For example, “production date” may stand for the off-production line date for manufacturers, or ex-factory date for wholesalers. Different interpretations will not only cause confusion but also block traceability. Therefore, the definition of the acceptable meaning of each piece of information should be based on actual needs and ground on succinct and clear thinking. In addition, inconsistent data format may incur inefficiencies and confusions as well. For example, one product produced on 10 February 2009, can be recorded as 10/2/2009 or 2/10/2009 or 2009-10-02. Therefore, to enable information sharing across different systems, both the data semantics and format should be standardized.

Table 3. Information Distribution Guidance

Data Characteristics	Storage Location		
	Tag	Local Database	Central Database
Large volume		✓	✓
Frequent access	✓		✓
Enforced release			✓
Voluntary sharing	✓	✓	✓
Business sensitive	✓	✓	

Standardize the Interface between Different IT Systems. As the information may be stored in different IT systems, local or central, standardizing the interface among these IT systems enables data exchange and facilitates automatic information enquiry [29].

Information Exchange Standard. Practitioners should be aware that there are different information exchange standards available, such as ISO 18000, EPCglobal or uID [14,34]. No matter which one the supply chain chooses, all the parties should join the same one.

A common software specification for real-time events is EPC Information Services (EPCIS), which encompasses both interfaces for data exchange and specifications of the data itself [35]. It provides a precise definition of all types of EPCIS data and events: static data including class-level and instance-level, and transactional data including instance, quantity and business transaction observations.

DISCUSSIONS

In this article, we present detailed design considerations regarding an ID system, reader infrastructure, and IT system to guide the decision makers to design an effective supply chain tracking system in order to achieve desired benefits with minimum cost. Some of the design considerations aim to bring out hidden factors that the supply chain may be unaware of. Some end up being trade-off decisions. The key to the cost effectiveness is to notice various design concerns and try to balance them out. Some other issues, which are not discussed in detail but are also important for the success of a supply chain tracking system, are listed below.

Design Consideration Integration. The eight design considerations target different aspects of the supply chain tracking system, and the design decisions mainly depend on three factors: characteristics of supply chain, product, and information. Supply chain characteristics relate to different industry sectors, operation environments,

and processes. Product characteristics refer to different product materials, values, and sensitivities to environment. Information characteristics suggest different levels of information volume, risk and business sensitivities. If the design results based on those factors conflict, a trade-off is required. The final decision rests with budget constraint, the input from the decision makers, and the strategy of the supply chain.

Investment Estimation. When it comes to the investment of a supply chain tracking system, the costs which first come to mind are (i) hardware costs including tag, antenna, reader, sensors, printer/encoder, (ii) software costs including middleware and supporting IT system; and (iii) system implementation, integration, and maintenance costs. Most of those are tangible and are one-time fixed investments.

The challenges of the cost estimation lie in two aspects. First, some of the above-mentioned costs may be underestimated. For example, RFID middleware has not reached the “plug-and-play” stage in the current market for most applications. Therefore, some initial adopters need to spend considerable effort and money on integrating the RFID system with their existing IT system and business process.

Secondly, rather than underestimation, there are some hidden costs that are more likely to be ignored and become a hazard for investment [25]. After implementing the tracking system, daily operation and management for each party may need some changes to fit into the new system. At the same time, the operators and even the managers need some training to better understand the new system in order to take full advantage of it. All these changes incur cost, and some are exorbitant, depending on the change extent. During the system implementation and operation, the supply chain may face various complex problems and has to turn to experts from consulting companies as these problems are usually beyond their expertise. In addition, subscribing to a service incurs a service provider fee. For example, some small to medium size companies cannot afford to design their own information

exchange platform, and have to pay to share a commercial exchange platform with others.

Close-Loop or Open-Loop Implementation. For barcode systems, the current practice is open-loop implementations. Customers can see one barcode for every product they purchase. When it comes to RFID, the lowest tag price in the current market is around 10 cents, which is a luxury for most commodities for item-level or even carton-level attaching. In this case, close-loop implementation may be a feasible alternative as the tags are reused. One example could be inventory management for shrinkage reduction or efficient management. One RFID tag is attached to one keeping unit, and the related information is recorded when the unit enters the warehouse and is unattached when it leaves. This closed-loop system recycles the RFID tags, and therefore largely cuts down the tag cost. However, it incurs the cost of additional tag handing and information recording for every replenishment.

Human Factors. To ensure the success of a tracking system, human factors are also critical. Firs, Ngai *et al.* [14] notes that to secure the senior management's support and understand their requirements and needs is the first step towards success as they can commit resources, personnel and time to the project. Secondly, a supply chain tracking system is not an internal system; every party needs to collaborate with others to gain system effectiveness. Retaining effective coordination with other partners paves the way to success.

DESIGN FOR MANUFACTURING AND ASSEMBLY

BABAR M. KORAISHY
KRISTIN L. WOOD
ANDREW TILSTRA
Mechanical Engineering
Department, University of
Texas at Austin

Historically, an enterprise would consider two basic functional entities for creating a product or system idea and evolving it into an actual physical realization: design and manufacturing. Design activities were typically initiated with a detailed identification of requirements and specifications. A range of concepts were then developed around these requirements. The selected concept(s) was further refined, and an overall spatial layout was developed in the embodiment phase. This layout of the design would then proceed into the detailed design phase where materials are selected, geometry (dimensions, shape, tolerances, and surface finish) is specified, different components are iteratively modeled for performance, and final drawings are developed which are ready to be handed over to manufacturing.

Once the manufacturing department received the design, they would typically study it, define material and processing requirements, develop process plans, develop tooling and fixtures as required, test and optimize the process setup, and initiate production. The entire process from design to manufacturing was, historically, sequential in nature.

Traditionally, design and manufacturing departments worked in relative isolation from each other, and, after evolving a design to engineering drawings, the “design” would be thrown “over the wall” to the manufacturing department as shown in Fig. 1. The manufacturing department would then be left to comprehend the design after all primary design choices had been made. If manufacturing found a problem in fabricating certain aspects of the design, the design would be handed back to the design team, and a lengthy redesign process would be initiated.

This serial process led to considerable inefficiencies, time delays, and high costs [1,2].

Efforts to alleviate and overcome this “serial” approach in engineering activities led to the practice of “concurrent engineering” (CE). CE examines a product development cycle as shown in Fig. 2, and emphasizes the need to implement important considerations of downstream processes, such as manufacturing and testing (and service, disposal, recycling, disassembly, and refurbishing) during the design phase. CE encourages parallel design activities, which not only leads to refinements in the design but also reduces the “time to market” of the resulting product or system. This parallel or concurrent approach to design is achieved by developing cross-functional teams, where the design team continually interacts with area experts such as manufacturing, testing, and so on [3,4].

Such an interaction with manufacturing has further evolved into an area known as *Design for manufacturing and assembly* (DFMA). Design for manufacturing (DFM) and design for assembly (DFA), or collectively known *DFMA*, applies generally across an enterprise’s approach for developing a product or system, including both business and engineering practices. For the purposes of this article, we will consider an engineering design focus of DFMA as entailing the guidelines, tools, and techniques to improve the manufacturability and assemblability of products or systems.

DFA, as a collective set of techniques, is used to study a design and simplify the part interfaces, with the intention of making components easier to assemble. An effective level of assemblability is achieved by refining components in a design such that redundant parts are removed, and such that the remaining parts are evolved to the point where separate parts have clear functional purposes. Effective assemblability of a product or system directly translates into a reduction of assembly time and hence a reduction in assembly costs.

DFM is the study and advancement of a design where each part is examined and refined from a process choice, part feature, and tooling standpoint. DFM techniques

Figure 1. “Over the wall” approach to design and manufacturing.

are intended to evolve individual parts to minimize the number of manufacturing processes and process steps, while creating design features of the individual part (within constraints of their intended function) so that they are less expensive to fabricate.

Assembly techniques have received considerable emphasis over recent years, as the potential for significant improvements in product assembly time and associated profit margins have helped spread DFA interest into business entities [5]. Assembly processes typically account for between 40 and 60% of the overall production time for a product or system [6]. As a result, industry has focused on assembly processes through studies of time and motion and division of work, as well as the use of robotics and automation.

Particular advancements in DFA emerged from many national and international research efforts. Boothroyd and colleagues, for example, published an original product DFA manual in 1982 [1,7,8]. This manual is regarded as the pioneering work of DFA techniques. It is composed of a formalized, systematic approach that includes selection of an assembly method—manual, high-speed-automatic, or robotic assembly, followed by an analysis of the assemblability of a design using a DFA worksheet. The worksheet (or associated software product)

takes into account factors such as handling time, geometries, insertion time, and theoretical minimum number of parts to provide for an evaluation of the “design efficiency” of products or systems. Besides Boothroyd and colleagues, many others have contributed to the field [9–17].

In recent years, DFM has also drawn considerable attention. Industries have invested a great deal of effort and resources into new manufacturing techniques, such as gas-assisted injection molding, powder metallurgy, and laser beam machining [18]. DFM software packages such as computer-aided process planning (CAPP) have provided engineers with tools during the various design stages [17–22].

DESIGN FOR MANUFACTURING AND ASSEMBLY CONSTRUCTS: OVERVIEW AND MOTIVATION

DFMA techniques are tremendously important for any product or system design activity. Such techniques result in significant cost savings, which are achieved by reducing part count, simplifying the part interfaces so that components are easier to assemble, and creating parts that are efficient to manufacture. By refining the design of individual parts, potential manufacturing flaws or features

Figure 2. Product development cycle.

that cannot be economically manufactured are removed or replaced. A subsequent benefit of this activity is that part quality is also improved. Another important benefit is that, since area experts in manufacturing are intimately involved with DFMA activities, manufacturing planning can be accomplished in parallel with the design activity, which affects the overall cycle time of a project where less time is spent in redesign and iteration.

For the purposes of this article, we consider a two-part construct to DFMA. The first construct considers DFA and DFM guidelines, where a guideline is a heuristic, rule, or generally proven directive for simplifying a component for manufacturability and assemblability. Designers and design teams may apply guidelines to concepts and existing products or systems for systematic improvement. The second construct is the application of force flow analysis. Force flow

Figure 3. Exemplar plot showing reliability improvements when applying DFA.

analysis considers the systematic mapping of applied forces or efforts to a concept, existing product, or existing system to identify the degree of freedom and relative motion between components due to the flow of applied forces. Through this analysis, insights may be obtained as to the functionality of components and the identification of possibilities for direct combination of components for product or system simplification.

Historical Example

In the late 1980s, Motorola introduced a new vehicle-mounted remote radio for base-remote communication. Their product at the time, the MX Converta Com, had 217 distinct parts requiring over 2700 s of assembly time. Motorola redesigned the product using DFM and assembly methods, and reduced the part count to 97 with 1350 s of required assembly time, an 87% reduction in direct cost. The number of screw fasteners was reduced from 72 to 0 [23]. Similar results were achieved for other Motorola product lines. Figure 3 shows an exemplar plot of number of defects as a function of Manual Assembly Efficiency following the Boothroyd and Dewhurst method [1]. This plot effectively illustrates the improvement in reliability that is possible using DFA techniques.

DESIGN FOR MANUFACTURING AND ASSEMBLY APPLICATION

Design Process

It is important to very briefly introduce the product/system design and development process, so as to enable further discussion on how and at what stage in the design process DFMA techniques may be applied. An engineering design process is the set of engineering activities that are employed to transform an idea, a concept, or a business goal into a tangible physical product that meets defined customer needs and requirements. Besides other activities, the two functional activities that are relevant to the present discussion are design and manufacturing.

A typical design process can be classified into three main types as follows:

1. Original design
2. Redesign
 - a. Adaptive design
 - b. Variant design
3. Product/System benchmarking

Original design refers to those design problems where solutions result in the creation of new marketplaces or the significant expansion or redefinition of current marketplaces. Redesign, on the other hand, entails

Figure 4. Application of DFA and DFM in the original and redesign process.

the evolution of a current instantiation of a product or system. Redesign involves two subtypes. In adaptive redesign, the essence of an existing design is adapted through the addition of new or enhanced functionality or the implementation of new technologies to replace current functionality. Variant redesign involves taking an existing design and evolving it parametrically, such as the scaling or reorganizing components to satisfy new requirements, or basic changes in geometry or material properties to improve product performance. A benchmarking design activity is actually not a creative activity but is typically employed to study an existing design, and quantify its performance, cost, and so on relative to competitors' designs or analogous designs.

Design for Manufacturing and Assembly Application in the Design Process

DFA techniques are typically applied before DFM techniques because DFA activities typically lead to the elimination of redundant parts, and/or lead to the significant modification of the features and functions of others. In the overall design processes (original and redesign) shown in Fig. 4, DFA is employed at the "embodiment design" stage. Embodiment design is the stage when a final selected concept is transformed into a physically realizable design with spatial form. It need not be the final form (as developed in detailed

design), but components, their functions, and layout are defined in the embodiment design stage.

Once a design reaches the detailed design stage, the physical form of every part is decided, performance modeled, materials and manufacturing processes selected, and all necessary engineering tasks are completed. This stage is the point where many design for manufacturing techniques are typically applied to the design to further refine it and eliminate any potential problems which might surface downstream in manufacturing or testing.

BASIC DESIGN FOR MANUFACTURING AND ASSEMBLY TECHNIQUES

Design for Assembly Guidelines

Figure 5 shows a basic view of a product assembly process. The different stages defined in the assembly process are part storage, part handling, insertion and position, and finally joining and fastening. DFA guidelines are basic heuristics and rules that aid the designer or design team in evaluating a design so that opportunities for improvement can be identified. A typical application of the guidelines, once a design concept(s) has been selected and preliminarily embodied, is for a designer or design teams to study the design

Figure 5. Assembly process.

as per every guideline, one by one, and modify the design until it satisfies the guidelines. It should be noted that all guidelines may be difficult to satisfy simultaneously depending on the desired functionality, potential manufacturing processes, and geometric layout of a product or system. Because of

this difficulty, as many guidelines should be applied as possible, resulting in alternative component layouts and geometries that are evaluated by the designer or design team.

Table 1 shows a list of DFA design guidelines [2,7,12,20,24–26]. These guidelines are

Table 1. DFA Design Guidelines

<i>System guidelines</i>	
1	Standardize components and interfaces to reduce part variety
2	Modularize multiple parts into single subassemblies
3	Assemble in open space, not in confined spaces. If possible, never bury Important components
4	Reduce part count by incorporating multiple functions into single part (function sharing)
5	Maximize part symmetry
6	Create features on parts or components to identify how to orient them for insertion
<i>Storage and handling guidelines</i>	
7	Prevent nesting of parts
8	Eliminate tangly parts
9	Color code parts that are different but shaped similarly
10	Provide features so that parts can be gripped properly
<i>Insertion and positioning guidelines</i>	
11	Provide orienting features on nonsymmetries
12	Insert new parts into an assembly from above (top-down assembly)
13	Insert parts or components from the same direction, or minimize the number of assembly directions. If possible, never require the assembly to be turned over
14	Provide alignment features on parts or components
15	Design in geometric or weight polar properties if a component or subassembly is nonsymmetric
16	Design mating features for easy insertion of components
<i>Joining and fastening guidelines</i>	
17	Eliminate fasteners
18	Use permanent or semi permanent fastening methods (such as welding, soldering, shrink fits) for joints that will require minimal disassembly
19	Allow proper spacing for fastening tools
20	Provide flats for uniform fastening and fastening ease
21	Place fasteners away from obstructions
22	Deep channels should be sufficiently wide to provide access to fastening tools. The use of no channels is preferred

organized as per the assembly stage to which they apply.

System Guidelines. The set of system guidelines shown in Table 1 apply to the overall product or system design and not to any specific stage of assembly. The first guideline indicates that, by reducing part variety, one can not only reduce assembly time but also reduce the logistics and inventory of maintaining a multitude of parts in stock. A good example for this particular guideline would be fasteners.

Breaking down a design into modules, as recommended in the second guideline, makes the assembly process more manageable and also influences quality control, as subassemblies can be individually tested rather than the entire assembly be tested for defects.

The third guideline recommends that one should not design a product where assembly would require one to reach into tight spaces with assembly tools. A product should be designed such that, during assembly, joints and fastening positions are easily accessible.

The fourth guideline urges the designer or design team to reevaluate the design and reduce the part count. There are a few different methods to do this, one of which is the force flow analysis, which is discussed in the subsequent sections.

The fifth guideline suggests that the designer should maximize part symmetry in a design so that part orientation becomes redundant. If it is not possible to create or fabricate a symmetric part, then the asymmetry should be made as obvious as possible, so that the correct orientation is obvious during assembly, and the assembler does not waste significant time in discovering the correct orientation.

The last system guideline suggests that having self-locating features designed in individual parts facilitates the assembly process, by eliminating the time spent in aligning parts. Exemplars illustrations of this and other DFA system guidelines are shown in Table 2.

Handling and Storage Guidelines. The next category of DFA guidelines is handling and

storage guidelines (Table 3). The first guideline recommends that features be built into the part that will prevent nesting. Nesting means that, when parts that are stacked on top of each other, there exists the potential that the parts will be difficult to assemble at nesting interfaces or may bind at these interfaces. Such nesting hinders their handling and storage and adds to assembly time.

The second guideline suggests that parts be designed such that they do not tangle or stick together. This hazard is especially apparent for wire harnesses, coil springs, and small components. Untangling and separating components can waste significant amounts of time and may lead to defects.

The third guideline suggests color-coding parts that are of similar shape and size so that they are easily identifiable by their color and less time is spent in identifying them during the assembly operation.

The fourth handling and storage guideline suggests that parts which are difficult to grip should have features built into them so that it becomes easier to handle them.

Insertion and Positioning Guidelines. The next category of DFA guidelines is insertion and position guidelines (Table 4). The first insertion and positioning guideline suggests that orienting features be built into nonsymmetrical parts so that the inherent asymmetries in the part can be aligned for mating. Often such features are not automatically designed when asymmetrical parts are designed, and existence of such features reduces assembly time.

The second guideline recommends that parts be designed such that top-down assembly is possible. In the case of a bottom-up assembly, the assembler would be fighting gravity when positioning and aligning parts, which increases the workload and assembly time. Alternatively, in top-down assembly, gravity will aid in part positioning and alignment. Designing a stable base part onto which other parts are attached from the top is recommended.

The third guideline is linked to the previous guideline. There exist many cases where

Table 2. DFA System Guidelines—Illustrations

Don't  Do  Standardize to reduce part variety (a)	Don't  Do  Design open enclosures to permit assembly in open space, not in confined spaces. Never bury important components (b)
Don't  Do  Modularize multiple parts into single subassemblies (c)	Don't  Do  Part count can be reduced by implementing multiple functions into single parts (d)
Don't  Do  Maximize part symmetry (e)	Don't  Do  Parts should easily indicate orientation for insertion (f)

Table 3. DFA Handling and Storage Guidelines—Illustrations

Don't  Do  (a) Prevent nesting of parts	Don't  Do  (b) Eliminate tangly parts
Don't  Do  (c) Color code parts that are different but shaped similarly	Don't  Do  (d) Provide features so that parts can be gripped properly

a top-down assembly approach is not possible or preferred. In such cases, it is recommended to have as few part insertion directions as possible, because for every new direction, either the assembler has to reposition himself or herself, or the product assembly has to be reoriented. A primary direction for assembly and, at most, one more reorientation are recommended to complete a product or system assembly. Continual reorientations significantly add to assembly time, especially with respect to the cognitive requirements placed on an assembler.

The fourth guideline indicates that alignment features be built into a product or

system design. This guideline seeks, upon insertion of part components into an assembly, that there exists automatic alignment of components, without the need for any measurements or the need for a component to be temporarily held in a position while it is fastened.

The fifth guideline suggests that asymmetrical parts be designed such that they can be easily oriented, especially those designed for automatic assembly where weight polar properties can aid in orientation during assembly.

The last insertion and positioning guideline recommends building in features such as

Table 4. DFA Insertion and Positions Guidelines—Illustrations

Don't  Do  Provide orienting features on non-symmetries (a)	Don't  Do  Insert new parts into assembly from above (b)
Don't  Do  Insert from the same direction, or very few. Never require the assembly to be turned over (c)	Don't  Do  Provide alignment features (d)
Don't  Do  For automated assembly, design in weight polar properties across non-symmetries (e)	Don't  Do  Design the mating features for easy insertion (f)

chamfers and fillets to make them tolerant to any variation in the assembly process. Such features will guide the part into its mating condition during insertion and will overcome manufacturing process variations.

Joining and Fastening Guidelines. The final category of DFA guidelines is joining and fastening guidelines (Table 5). Joining or fastening is typically the last stage in an assembly process. Once a part has been inserted into an assembly and positioned in the required location, it must be fixed to the remainder of the assembly. This process requires access for tools or sister components so that the part can be secured. The guidelines provided in this section identify steps a designer or design team can take to facilitate the joining and fastening stage in the overall assembly process in an efficient and cost-effective manner.

The first guideline suggests the removal or reduction of as many fasteners as possible (without compromising the structural integrity of the assembled part). Fasteners such as screws, nuts, and bolts require a certain time to be properly assembled, and if they can be replaced with quick-insert-type joints, quick connects, or architecture alignment and securing forces, then time savings can be reached, as well as a reduction in overall part count.

The second guideline recommends that components that will not be frequently disassembled can be potentially be joined via a permanent or semipermanent joining method, such as welding, soldering, adhesives, riveting, and so on. These joints are typically less expensive to install, but the cost of removal is much higher (potentially impacting disassembly, recycling, repair, refurbishing, and reuse).

The third guideline suggests providing adequate spacing between fasteners so that there is adequate space for a tool to access the fastener and the material integrity is not compromised by leaving inadequate material between joints.

The fourth guideline suggests that fasteners should not be fastened against angled surfaces. If angled parts are to be joined, then the designer or design team should design

parts that have machined “flats,” where, for example, a bolt head can sit and secure the assembled parts.

The fifth and sixth guideline are closely related. The fifth guideline requires that fasteners be placed in positions where they can be easily accessed for removal, without any special tools. The sixth guideline recommends that if fasteners are to be placed in pockets or channels, they must be wide enough to provide access to tools.

Design for Manufacturing Guidelines

DFM guidelines, much like their DFA counterparts, provide heuristics and rules for improving the manufacturability of components for products and systems. Tables 6–10 provide representative and key guidelines for DFM. These guidelines are dependent on particular manufacturing processes. The guidelines shown in the following tables cover typical and highly applied manufacturing processes in industry. Specific manufacturing references are available for specialized manufacturing processes or other manufacturing processes beyond those represented by Tables 6–10.

DFMA Force Flow Analysis

Building upon the DFA and DFM guidelines, the next basic technique for DFMA is known as *force flow analysis* (or more generally as *effort flow analysis*). Force flow analysis encourages evolution in components of products or systems from the mechanical energy domain by identifying component combination opportunities that are achievable using rigid body and/or compliant mechanisms [20,27–29]. Force flow analysis uses a force flow diagram to represent the transfer of force/effort through product or system components. The force flow diagram is a semantic network composed of nodes and links that are described using the fundamentals of graph theory [30,31]. The nodes of the diagram represent the components of the product or system, while the links represent the interfaces between the components.

Whenever possible, force flow diagrams are laid out in such a manner that the general topology of the product is depicted in

Table 5. DFA Joining and Fastening Guidelines—Illustrations

Don't  Do  (a) Eliminate fasteners	Don't  Do  Nut and screw replaced by rivets Use permanent or semi permanent fastening methods (such as welding, soldering, rivets) for joints that will require minimal disassembly (b)
Don't  Do  Proper spacing insures allowance for a fastening tool (c)	Don't  Do  Providing flats for uniform fastening and fastening ease (d)
Don't  Do  Place fasteners away from obstructions (e)	Don't  Do  Deep channels should be sufficiently wide to provide access to fastening tools. No channel is best (f)

Table 6. DFM Guidelines—Mold Processes

Don't  Stepped thickness transition Do  Better  Best Make all transitions smooth and avoid changes in thickness when possible (a)	Don't  Potential sink marks and voids Do  Attach bosses to walls with ribs Gusset free standing ribs (b) Keep section thickness uniform around bosses															
Don't  Voids Sink marks Do  $t_{rib} \equiv \frac{1}{2t}$ 3t min Keep rib thickness less than 60% of the part thickness to prevent voids and sinks (c)	Don't  Sharp corner Do  $R = \frac{3}{8}t \geq 0.06$ Avoid sharp corners, they produce stress concentrations and obstruct material flow (d)															
Don't  No Draft Do  2° min Always provide a draft angle for easier mold removal (e)	Don't  $t < 4\text{mm}$ Do  Use ribs instead $0.065'' \leq t \leq 0.5''$ Minimize section thickness, cooling time is proportional to the square of the thickness of the parts(s), and reducing the cooling time directly reduces costs (f)															
General Tolerances (mm) <table><tr><th>From</th><th>To</th><th>±</th></tr><tr><td>0</td><td>25</td><td>±0.5</td></tr><tr><td>25</td><td>125</td><td>±0.8</td></tr><tr><td>125</td><td>300</td><td>±1.0</td></tr><tr><td>300</td><td></td><td>±1.5</td></tr></table> Use standard dimensional variation capability: Do no tolerance (g)	From	To	±	0	25	±0.5	25	125	±0.8	125	300	±1.0	300		±1.5	 0.005" Use standard thickness variation capability; do not over tolerance (h)

the topology of the diagram. As an example, a force flow diagram for a Staple Remover product (Fig. 6) is shown in Fig. 7. Notice in the figure that finger forces enter, for the operation of removing a staple from a set of papers, the top and bottom pad and flow

through the components of the product to work on the staple (work piece) and to store energy in the torsion spring for returning the stapler remover jaws after the operation is complete. The main benefit of modeling a product using a force flow diagram is the

Figure 6. Staple remover product, 10 components/parts.

Figure 7. Force flow diagram of staple remover product (input finger forces).

identification of possible component combination opportunities. These opportunities are made more obvious when the relative motion at the interfaces between connected components is characterized. Characterizing the relative motion entails labeling the links between components. The links model the interaction between components, and are the conduit for force flow (force or torque transfer in the mechanical domain). Labels are added to the links to identify relative motion characteristics across the link. The labels on links between connected components are defined as follows:

“N”: no relative motion between components.

“R”: relative motion at the interface and between other component regions.

Figure 8 shows the labeled links for the force flow diagram of Fig. 7. The “R” label is used to denote an interface where “relative motion occurs both between the extents of connected components as well as at the physical interface between the components (i.e., the nodes).” Once characterization of relative motion and link labeling is completed, the following guideline applies:

Figure 8. Force flow diagram of staple remover product with link labels and part groups.

Force flow guideline: Groups of components where no relative motion exists (no R-Links connecting members within the group) are candidates for combination if not prohibited by material or assembly/disassembly issues.

Combination between components or component groups that are connected by R-Links may be possible, but will require more complex redesign. This guideline suggests that parts that do not experience relative motion are direct candidates for combination and that parts that do experience relative motion may still be candidates for combination but will require compliance or other creative steps to obtain equivalent functionality.

The next step in constructing an effort flow diagram is to identify groups of components connected by non-relative-motion links (N-Links). These groups of components are the starting point for further investigation of component combination. They suggest direct combinations through the force flow analysis, providing opportunities that may not have been intuitive or otherwise considered by a designer or design team. Figure 8 shows the groupings of components that may be

considered directly. In particular, due to the symmetry of the product, the pads, rivets, and jaws on the top and bottom of the product, these parts may be considered for combination, such as through molding, sheet metal, or casting manufacturing processes.

Summary: Force Flow Analysis Process.

Based on this description of force flow analysis and force flow diagrams, the DFMA process for this technique maybe summarized as follows:

1. Choose a concept or existing product/system to model.
2. Identify the operation(s) of the concept, product, or system to model.
3. Identify the input or internal forces and torques for the chosen operation(s).
4. Create a force flow diagram of the concept, product, or system, starting with the input and internal forces and torques, and following these forces and torques through until they terminate and/or create reaction forces.

Table 7. DFM Guidelines—Sheet Metal Forming Processes

 (a)	 (b)
 (c) Position openings away from bends	 (d) Position holes away from bends
 (e) Shear and form operations should have a minimum height (h) of 2½ the blank thickness	 (f) Avoid sharp corners, or the material will tear

- Assess each flow between components, and label the flow links with “N” or “R.”
- Identify all groups of components connected by non-relative-motion links (N-Links) with no intermediate R-Links.
- Create concepts to combine the components in each component group while maintaining the functionality of the groups. Consider alternative manufacturing processes for the new component group concepts.
- (Optional) Consider component combinations across R-Links. For example, where relative motion exists between components (but not at the interfaces), consider compliant structures to achieve the component functionality while combining components. Examples of this situation are when

Table 8. DFM Guidelines—Sheet Metal Forming Processes II

Don't  Do  Use separated straight flanges where possible (a)	 If $D \geq 2t$, A cutout is needed to bend flange (b)
Don't  Do  A narrow web will cause bulging. Provide an ear in the blank or include the hole as a notch (c)	Don't  Do  Offset bends (d)

Table 9. DFM Guidelines—Casting Processes

Don't  Do  (a) Maintain section thickness uniform	Don't  Do  (b) Provide a draft angle to help removal from mold
Don't  Do  (c) Avoid sharp corners	Don't  Do  (d) Design bosses with uniform thickness
Don't  Do  (e) Avoid abrupt changes in section thickness	Don't  Do  (f) Stagger ribs to prevent hot spots
Don't  Do  (g) Restraining a part of the casting produces tensile stresses that can result in hot tears	Don't  Do  (h) Non-uniform section thickness caused hot spots that causes shrinkage defects. Design T-junctions to prevent hot spots

Table 10. DFM Guidelines—Machining Processes

Don't $D = 0.627''$  Do $D = 0.625''$  (a) Use standard dimensions	Don't  Do  Design holes to the shape of tool. If hole is to be tapped, provide space for it (b)
 (c) Avoid long narrow holes	Don't  Thin wall Do  Avoid thin walls that break when machining (d)
Don't  Do  Don't  Do  (e) Avoid drilling inclined faces	Don't  Do  Don't  Do  Do not design impossible to machine hollows or overhangs (f)
Don't  Impossible Radius smaller than 1/4" Do  Use 1/4–1/2" radius Design for reasonable internal pocket radii (g)	Don't  Do  (h) Place holes away from corners and edges

Table 10. (Continued)

 (i) Design for reasonable internal pocket radii	Don't  Do  (j) Provide access for tools
Don't  Do  (k) Holes can't change direction	 (l) Deep pockets also cause vibration of the tool
Don't  Do  (m) Avoid outside rounds, which are difficult unless CNC-machined	Don't  Difficult to fixture Do  Easier to hold (n) Design parts that are easy to fixture

Figure 9. Evolved stapler remover with three parts (insert mold or adhesive jaws w/compliant joint).

springs are used, such as the torsion spring in the stapler remover product (Figs 7 and 8).

and a compliant (living) hinge is created at the right region of the product to replace the torsion spring and pin.

Figures 6–9 show the application of the force flow analysis to the stapler remover product. Figure 9 shows a developed concept which reduces the original 10 components of the product to three components. An insert mold is used to create the pad-jaw structures,

PRODUCT APPLICATION: CORDLESS SCREWDRIVERS

To demonstrate the utility of DFMA techniques discussed in this article, an industrial

Figure 10. Industrial cordless screwdriver product, illustrating different stages of disassembly.

product, a cordless screwdriver, is selected and analyzed. The product operates with four AA batteries and accepts screwdriver bits. Figure 10 shows the disassembly of the product. Figure 10a shows the product with its AA battery pack and screwdriver bit removed. In Fig. 10b the housing is opened up by the removal of two screws and the internal components of the driver are visible. The key components easily identified here are the DC motor and the necessary planetary gear train which reduces the rotational speed and increases the torque. Figure 10c shows additional components, which are shown in greater detail in Fig. 10d. These components include a battery connector, the direction switch, and a battery terminal plate.

Subtract-and-Operate Procedure (SOP). A bill-of-materials (BOM) for the cordless screwdriver product is shown in Table 11. A subtract-and-operate (SOP) procedure was applied to the product, and the effect of removal of each part is identified in the table. This process simply considers the systematical removal and replacement of a component of the product to deduce the functionality of each component and its affect of the product's mechanical degrees of freedom [20,28]. As shown in the table, there are no obviously redundant parts. The product is well designed at this level, and it is apparent that the designers kept manufacturing and assembly in mind while designing the product, especially in terms of part count (such as with fasteners).

Force Flow Analysis. Force flow diagrams represent an invaluable tool when a designer or a design team seeks to identify opportunities for part assimilation and the overall simplification of the design. A force flow analysis was performed on the product and the results are shown in Fig. 11.

Three groups separated by R-links are identified. By analyzing Group 1, one can see that there are multiple energy/effort flows, electrical energy as well as mechanical energy. The battery plugs into a battery connector, and current is conducted via terminals into wires (see BOM, Table 11) and into the switch plate. When the direction

switch button of this product is pressed, the DC motor is energized. Potentially, these components, as shown in Fig. 11, could be combined. In the current product, Group 1 contains 17 parts.

Group 2 contains the DC motor and the motor spur (pinion) gear. These components are already a basic module without fasteners, and they can typically ship together as one unit from an original equipment manufacturer.

Group 3 includes three parts: the shaft coming from the gear train, the chuck that accepts bits, and the bit itself. Potentially these three components could be combined, but then the product would be limited to one single bit, and not accept other bits for different screw heads. This combination would limit functionality and would be infeasible (except for perhaps the subcombination of the shaft and chuck).

Of the three components groups and redesign avenues explored through force flow analysis, the first group appears to be the most promising. A number of concepts may be developed for this component group at this stage. However, we will expedite and systematically explore concepts by using DFMA guidelines.

Application of DFMA Guidelines

Device Function. The components identified for redesign are shown in Fig. 12. The first region of the figure shows how the parts are assembled in the current product, and the bottom region of the figure shows the completed assembly (excluding other components not under study).

On the basis of Fig. 12, the way the system works is that the battery pack plugs in from the back, and upon insertion into the product, the battery pack terminals make contact with a battery connector jack (as shown in Fig. 13c). The metal battery connector terminals have wires soldered onto them that are connected to the switch plate. The switch plate's function is to reverse the direction of current flow, depending on which side of the switch the user presses. When the direction switch button is pressed, metal switch terminals make contact with the corresponding switch plate terminals on the switch plate,

Table 11. Bill-of-Materials (BOM) and Effect Table—Cordless Screwdriver Product

	Module/ Part #	Qty	Mfg. Process	Material	Effect of Removal
1	Battery holder	1	Injection molded	Plastic	Batteries are not held in place against the terminals.
2	Series terminal clip	2	Stamped and bent	Steel	Does not operate. Batteries not connected.
3	Battery connector	1	Injection molded	Plastic	Doesn't operate. Plug terminals are not pressed against battery clip.
4	Battery connector terminals	2	Stamped and bent	Steel	Does not operate. Switch and motor are not connected to batteries.
5	Series terminal plate	1	Stamped and bent	Steel	Does not operate. Batteries not connected.

Figure 11. Force flow analysis of a cordless screwdriver product.

and the circuit is completed. Current is then carried through wires, which are connected to the switch at one end and to the DC motor at the other end. Figure 13 shows the three modules under discussion. The direction switch button has five parts. The switch plate, Fig. 13b, has six parts, and the battery connector is made up of three parts. Besides these modules and parts, four wires are also used to connect between these parts and the motor.

DFA Guidelines. DFA guidelines were employed in the redesign on the subassemblies shown in Fig. 13. The first guideline employed, as shown in Table 12, is a system guideline that suggests that multiple parts be incorporated into a single subassembly, and the second suggests that part count be reduced by incorporating multiple functions in a single part. With these suggestions in mind, the following concept (Fig. 14) was conceived.

Figure 12. Cordless screwdriver product, isolating components for redesign.

Table 12. DFA Guidelines Applied to the Cordless Screwdriver Product

1	Modularize multiple parts into single subassemblies
2	Reduce part count by incorporating multiple functions into single part
3	Eliminate tangly parts
4	Provide features so that parts can be gripped properly
5	Provide alignment features
6	Design the mating features for easy insertion
7	Eliminate fasteners
8	Use permanent or semi permanent fastening methods (such as welding, soldering, shrink fits) for joints that will require minimal disassembly

Figure 13. Cordless screwdriver product, showing particular components from Fig. 12.

Figure 14. New component concept for cordless screwdriver product.

This new part concept combines the functionality of the switch plate and the battery connector jack from the original cordless screwdriver (Fig. 13b and c) into one part.

Using the third and fourth guidelines in Table 12, the springs in the switch assembly (Fig. 13a) were eliminated. The springs in the original product return the switch button

back to its original configuration when the user is finished pressing it. This function was incorporated into another multifunction part shown in Fig. 15. These metal tabs are bent so that they act as a spring (flat or leaf spring), simultaneously act as part of the direction switching circuit, and act as connector terminals to the motor (making obsolete the need for wires).

Figure 15. Additional new component concepts for cordless screwdriver product.

Figure 16. Overall component concepts for cordless screwdriver product.

Alignment features were provided as suggested in guideline 5 from Table 12 by providing grooves where these metal tabs will connect and be joined using permanent fastening methods as suggested in guideline 8 from the same table. The fastening method chosen for this application is a heat-staking process. The overall design, integrating the new component concepts, is shown in Fig. 16.

Grooves built into the design provides features for easy insertion, and two screws were eliminated by using friction pins as shown in Fig. 17. The two other tabs act as the battery connector jack terminals as well as the direction switching circuit. This arrangement eliminates the need for wires and soldering. The total part count of the assembly has been reduced from 17 to 5 by this design.

Figure 17. New housing concepts based on DFM guidelines as applied to cordless screwdriver product.

Figure 18. Overall design of new components for cordless screwdriver product based on the application of DFMA techniques.

DFM Guidelines. DFM guidelines for injection-molded parts were also employed when desinging the new component concepts. Draft angles were provided for easier mold removal, and sharp corners were minimized and free-standing ribs were used, where possible. The new design also utilized the removal of extraneous ribs, as shown in Fig. 17. The overall assembly of the new design is shown in Fig. 18.

CONCLUSIONS AND GOLDEN NUGGETS

In this article, we explored the contemporary business and engineering topic known as *DFMA*. At an enterprise level, *DFMA* is pervasive and reaches across organizational structures. In our exploration here, we have scratched the proverbial “tip of the iceberg” of *DFMA*; however, a set of guidelines and techniques have been constructed for effectively transforming design concepts and existing products and systems to efficient designs that have great potential for competitive advantage through cost savings, increased reliability, and innovative component structures. The basic techniques presented in this chapter do not replace the designer in creating efficient designs in terms of manufacturability and assemblability: instead, novel insights are provided that enable designers and design teams to identify new and innovative component concepts that would possibly not be explored through *ad hoc* approaches.

DESIGN FOR NETWORK RESILIENCY

MICHAEL TORTORELLA
Rutgers Center for Operations
Research, Rutgers University,
Piscataway, New Jersey

FOREWORD

Rationale

In the beginning there was the social network. From the earliest days of *Australopithecus* and *homo erectus*, individuals formed complex webs of social interactions that we today conceptualize as networks. It is no exaggeration to say that these networks enabled the species to survive and evolve into today's humans who are capable of such conceptualization. Until roughly the Renaissance, mostly that is all there was, when the advent of sailing ships and intrepid sailors enabled goods to be moved greater distances. This, and further advances during the nineteenth century, begat the supply chain network, although, again, no one used that name at the time. The invention of the telephone in 1876 begat the telecommunications network. The postal system, the electric power grid, and commodity networks such as oil and gas transport systems brought forth a new way of life. Indeed, civilization as we know it would be impossible without networks.

In the twentieth century, mathematicians began to study networks as abstract objects to do a better job of creating and improving them. Our position in this paper is that networks are not ends in themselves; they exist to perform certain functions. Society is interested in the continued performance of these functions at an adequate degree and at reasonable cost. The concept of *resiliency* is introduced to enable discussion of the degree to which the functions performed by a network continue to be performed when various disruptions occur. The purposes of this article

are to describe a mathematical framework for discussing network resiliency in quantitative terms and to list principles and practices that can be employed during the design of a network to promote its greater resiliency.

Scope

The material presented in this article is generic in the sense that it applies to all types of networks and is not restricted to a particular application. We consider networks that transport continuum materials such as oil and gas, and networks that transport discrete physical objects such as letters and packages as well as notional objects such as data packets in telecommunications. Social networks are also included in that they exist to share something among the individuals comprising the nodes of the network: information, or status, or power relationships.

We reserve for future consideration further development of an alternate property characterizing resilient networks, namely that they return quickly to a normal functioning state after a disruption. Again, a matter of degree is involved, and it will be necessary to develop quantitative models to treat this phenomenon adequately.

Background

The etymology of "resiliency" is the Latin *resilio*, which means "to leap or spring back." The informal use of the word stems from this origin. "Network resiliency" began to be used as a phrase because people wanted a way to express how well a network may continue to perform its intended functions when the inevitable degradation of operating conditions occurs, or how quickly it returns to normal operation after a disruption. Infrastructure degradation includes failures and/or loss of capacity of the network's constituent elements (switches, routers, valves, transport systems, etc.) that may be due to reliability problems (hardware, software, operations) in the physical equipment (pipes, wires, towers, circuit cards, trucks, buildings, etc.) mak-

ing up the network elements. These failures, in turn, may be due to “random” manifestation of broken or deteriorated components, or due to natural disasters such as earthquakes and fires, or due to deliberate attacks. The study of the effects of such failures on the network as a whole gives rise to the mathematical theory of network reliability [1,2], which usually considers figures of merit like two-terminal connectivity and all-terminal connectivity as indicators of the purposes of the network. The literature on the mathematics of network reliability is extensive.

In prior studies, “network resiliency” was used to convey a sense of continued satisfactory fulfillment of some purpose of the network in the face of failures and disruptions and/or the rapid return of the network to normal operation after a disruption. Specific purposes studied have included communication among node-pairs [3], survivability [4], the ability to provide alternate communication paths [5], reachability [6], economic damage [7], and disconnection of the network [8,9]. Occasionally, the term is used without specific definition, assuming that resiliency would be equated with “good” properties implicitly known to the reader, as in Ref. 10. In these cases, some specific measure of how well the network continues to operate, that is, provides its intended service(s), serves as the proximate interpretation of network resiliency. The generalization to delivery functions (see the section titled “Delivery Function”) and delivery importance (see the section titled “Delivery Importance”) is natural.

Resiliency and Reliability Contrasted.

Before proceeding further, some differences between resiliency and reliability are worth examining. The primary difference is that resiliency applies to the functions or services performed by the network, whereas reliability is usually used to describe the failure and repair behavior of network elements. One of the most important *delivery functions* (see the section titled “Delivery Function”) we use in defining network resiliency is the service reliability of the services or applications that run on the network (see Refs 11 and 12 for further clarification on service reliability),

but using service reliability as a delivery function is not the only reasonable approach to network resiliency characterization. In this article, we see that figures of merit and metrics for network resiliency depend on the particular delivery function associated with the network. The examples in the section titled “Three Examples of Delivery Functions” are specializations of the general theory presented in the sections titled “Delivery Function and Delivery Importance” and “Network Resiliency.”

In addition, network resiliency resembles reliability importance [13,14] more than plain reliability. In essence, network resiliency is an attempt to describe how the reliability of services that run on the network changes when certain parts of the network experience reductions in capacity (possibly stemming from equipment failures, natural disasters, deliberate attacks, etc.). Therefore, reliability is an important primitive concept in the construction of network resiliency measures, and such measures incorporate the change in reliability (broadly interpreted) as network conditions change.

Resiliency and Survivability Contrasted.

The related notion of survivability has been studied primarily in the telecommunications context [15]. The earliest approaches to survivability were mainly concerned with the provision of geographically diverse alternate routes so that traffic that would normally be carried on facilities that could be lost due to natural disaster or deliberate attack would continue to reach its destination [16]. While the amount of traffic that is successfully rerouted and carried is a key indicator of network resiliency, survivability studies did not necessarily explicitly incorporate measures of how much traffic would be successfully rerouted. Later studies began to incorporate such considerations [17], and thereby resemble more comprehensive resiliency studies.

Some care is required in interpreting the literature regarding reliability, survivability, and resiliency because these terms are sometimes used interchangeably with no warning.

Resiliency and Vulnerability Contrasted. In a sense, network resiliency is a more complete description of network operation under degraded conditions than network vulnerability. For example, certain network elements may be vulnerable to damage to a greater degree than other network elements, but if the consequences of damage to the former are minor in terms of, say, added congestion or other disruptions of the flow in the network, and the service consequences of this flow disruption are also minor, then the network may still be resilient even though vulnerable. General considerations aside, network vulnerability would have to be defined precisely, and in quantitative terms, in order to make valid comparisons. Any such definition has not yet received wide acceptance.

Synopsis

The approach taken in this article goes beyond that of the usual network reliability theory. To capture the notion that the network exists to perform a desired function, we define a *delivery function* associated with a network that tells what the network is being used for. The precise definition is given in the section titled “Delivery Function,” some examples of delivery functions here serve to provide a flavor of what this means. In the most general case, we may consider a delivery function to be the reliability of a service or application [11,12] to a user in the sense that is used in telecommunications networks: for example, a user pays an internet service provider (ISP) for access to the ISP’s network so that the user may acquire page views from the world wide web, upload files, and so on, and the reliability of those services as seen by the user/purchaser of the service is the delivery function. For a commodity network, such as an oil or gas transport network, the delivery function may be the quantity of commodity delivered to specified destination nodes over a stated period of time. In other cases, the delivery function can be as simple as the two-terminal connectivity in an uncapacitated network. The key idea is that the delivery function captures the essence of what the network is being used for.

Delivery importance of a subset of the network is then defined in terms of the change in the value of the delivery function when conditions in that subset change (e.g., increase or decrease in capacity or removal from service). A derivative comes into play here, and so delivery importance represents a generalization of the idea of reliability importance [13,14] to this broader context. *Network resiliency* is defined as the degree to which the network is sensitive to changes in its infrastructure: a network is resilient if there are “few” subsets that have “high” delivery importance. We then discuss three examples of particular delivery functions in increasing order of complication: connectivity, reliability, and flow in a stochastic network. We give examples of each and discuss computational issues.

Some design principles promoting greater network resiliency are reviewed in the section titled “Design for Network Resiliency Principles and Practices.” The two principles discussed are overprovisioning and network control. A straightforward network resiliency optimization problem is introduced in the section titled “Network Resiliency Optimization,” and the network interdiction problem is discussed in the section titled “Network Interdiction” as a converse to the network resiliency problem.

DELIVERY FUNCTION AND DELIVERY IMPORTANCE

Delivery Function

To enable discussion of network resiliency in quantitative terms, we associate with a network a function Ψ that we call the *delivery function*. The intent is that this function will express quantitatively the purpose of the network or the service that the network is intended to provide. It may be a function, such as connectivity, that is already familiar in network reliability theory, or it may be a function, such as service reliability, that has not previously been considered in this context. The delivery function associates a real number or a vector with the elements of the network.

A network $(\mathcal{H}, \Psi)$ with delivery function is an ordered pair consisting of a graph $\mathcal{H}$ and associated delivery function Ψ . $\mathcal{H} = (\mathcal{N}, \mathcal{L})$ where $\mathcal{N}$ is a set of elements, called *nodes*, and $\mathcal{L}$ is a subset of $\mathcal{N} \times \mathcal{N}$. We denote the number of nodes in the graph by $|\mathcal{N}| = N$. If, for $i_1 \neq i_2$ belonging to $\mathcal{N}$, $(i_1, i_2) \in \mathcal{L}$, then (i_1, i_2) is a link; if $i_2 = i_1$, then (i_1, i_1) is another way of writing the node i_1 . $\mathcal{N} \cup \mathcal{L}$ is the set of network elements and Ψ maps $\mathcal{N} \cup \mathcal{L}$ into the real numbers or a vector space, depending on the range appropriate to the particular case studied.

Delivery Importance

This section discusses delivery importance, the influence of a network element, or a set of network elements, on the delivery function. The concept of delivery importance is introduced to enable us to see how changes in the network element(s) are reflected in the delivery function, that is, how well the network continues to perform the functions expected of it when there are changes in the network infrastructure. We first consider delivery importance in deterministic capacitated networks, both continuum and discrete. Delivery importance is defined for uncapacitated networks by considering the presence or absence of nodes and/or links in the graph, and assigning probabilities in the case of a stochastic uncapacitated network; see the section titled “Delivery Importance in Deterministic Uncapacitated Networks.” We then extend the definitions to stochastic capacitated networks, both continuum and discrete.

Delivery Importance in Deterministic Capacitated Networks. The *capacity* of a network element is a nonnegative real-valued function $c : \mathcal{N} \cup \mathcal{L} \rightarrow \mathbf{R}^+$. The capacity may represent the presence or absence of a network element (in which case the range of the capacity function is $\{0, 1\}$), the probability that a network element is in the graph, or the *reliability* of the network element (in which case the range is $[0, 1]$), or it may represent what is commonly understood as capacity in a flow network [18]. Capacity may be constant (static network capacity) or a function of time (dynamic network capacity). We also

consider capacitated networks in which the capacities are random quantities (stochastic capacitated networks) as being distinct from deterministic capacitated networks in which the capacities are not random.

We define the *capacity matrix* $C(\mathcal{H})$ to be the matrix whose (i, j) entry c_{ij} is the capacity of the link (i, j) if (i, j) is a link ($i \neq j$), 0 if (i, j) is not a link ($i \neq j$), and the capacity of the node i if $j = i$. In capacitated networks, we consider the domain of the network’s delivery function to be the space Γ of capacity matrices $\mathbf{R}^{N \times N}$. Therefore, for example, a scalar-valued delivery function maps a capacity matrix $C(\mathcal{H})$ into $\mathbf{R}^+$. It is also possible to consider vector-valued delivery functions. These are important for applications, but the extension of the theory given here to vector-valued delivery functions is straightforward (Eq. 8); therefore, a full discussion of vector-valued delivery functions is not undertaken here. A generic capacitated network with associated delivery function may be denoted by $(\mathcal{H}, C, \Psi)$.

Delivery Importance in Deterministic Capacitated Continuum Networks. In a continuum network, the range of the capacity function is the nonnegative real numbers, and a flow in the network [18] may take on nonnegative real values as well (subject to the constraint that the value of the flow at any network element not exceed the capacity of that network element). Continuum network models describe networks that deliver continuum materials such as oil, gas, water, and electricity or social networks in which the weight on a link (its “capacity”) is the strength of the relationship between the two nodes it connects. In a continuum network, we assume that the delivery function is a continuously differentiable function of the capacities except possibly on a set of Lebesgue measure zero. That is, for each network element $(i, j) \in \mathcal{N} \cup \mathcal{L}$, the derivative $\partial \Psi / \partial c_{ij}$ exists, except possibly on a set of Lebesgue measure zero in the space Γ of capacity matrices, and is continuous as a function of the capacity wherever it exists. It is possible that this derivative may be zero; if so, the network element is “unimportant” to the delivery function. This is an analogue

of the notion of coherence [19] in the mathematical theory of reliability.

The main idea of delivery importance is to see how the delivery function changes when the network capacity changes incrementally. That is, we would like to compare $\Psi(C_0 + hA)$ to $\Psi(C_0)$, where C_0 is a nominal capacity matrix, or study value of the capacity matrix, A is a matrix representing a “direction” in which capacity increases (or decreases) form the basis of the study, and h is a real number, typically close to zero. The basic delivery importance equation for the single network element (i,j) is, for fixed $a \neq 0$,

$$\Psi(c_{ij} + ha) - \Psi(c_{ij}) = \frac{\partial \Psi}{\partial c_{ij}} \Big|_{C_0} ha + o(h), \quad (1)$$

where the remainder term satisfies $o(h)/h \rightarrow 0$ as $h \rightarrow 0^+$, provided Ψ is differentiable at $(C_0)_{ij}$. There is no loss of generality in taking a to be 1 or -1 . $a = 1$ (respectively $a = -1$) indicates the delivery importance when the capacity of network element (i,j) increases (respectively decreases). The one-term Taylor series expansion (Eq. 1) motivates the following definition.

Definition. For a differentiable scalar delivery function, the *delivery importance at C_0 in the direction a ($a = \pm 1$)* of a network element $(i,j) \in \mathcal{N} \cup \mathcal{L}$, denoted by $\Omega_a(i,j; C_0)$, is defined as the derivative of Ψ with respect to the capacity c_{ij} of the network element (i,j) , evaluated at the capacity matrix C_0 :

$$\Omega_a(i,j; C_0) = a \frac{\partial \Psi}{\partial c_{ij}} \Big|_{C_0}, \quad (2)$$

when it exists.

Combining this with Equation (1) yields $\Psi(c_{ij} + ha) - \Psi(c_{ij}) = \Omega_a(i,j; C_0)h + o(h)$ for $a = \pm 1$ and $h \rightarrow 0^+$.

Example 1. Consider the simple directed, capacitated network consisting of two links in series, shown in Fig. 1.

The three nodes each are considered to have infinite capacity and the capacities of

the two links are x and y , respectively. The capacity matrix for this network is

$$C = \begin{pmatrix} \infty & x & 0 \\ 0 & \infty & y \\ 0 & 0 & \infty \end{pmatrix}. \quad (3)$$

The delivery function for this network is defined as the maximum flow from node 1 to node 3, which in this case is $\Psi(C) = \min\{x, y\} = 1/2(|x + y| - |x - y|)$, $x, y \geq 0$. Here, Ψ is differentiable except on the line $x = y$. We have, for $x \neq y$,

$$\begin{aligned} D_1 \Psi(x, y) &= I\{x < y\} \text{ and } D_2 \Psi(x, y) \\ &= I\{x > y\}, \end{aligned} \quad (4)$$

so the delivery importance in the positive direction of the link (1, 2) is $\Omega_1(1, 2; C) = 1$ if $x < y$ and 0 if $x > y$, and that of link (2, 3) is 0 if $x > y$ and 1 if $x < y$. Define the nominal capacity matrix

$$C_0 = \begin{pmatrix} \infty & c_{12} & 0 \\ 0 & \infty & c_{23} \\ 0 & 0 & \infty \end{pmatrix}. \quad (5)$$

For this nominal capacity matrix, $\Omega_1(1, 2; C_0) = 1$ if $c_{12} < c_{23}$ and $= 0$ if $c_{12} > c_{23}$, and $\Omega_1(2, 3; C_0) = 0$ if $c_{12} < c_{23}$ and $= 1$ if $c_{12} > c_{23}$.

When $x = y$, the derivatives do not exist. Define

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \quad (6)$$

Then we return to the basic idea of delivery importance to write, for $h > 0$,

$$\begin{aligned} &\frac{1}{h} [\Psi(C_0 + hA) - \Psi(C_0)] \\ &= \frac{1}{h} [\min\{c_{12} + h, c_{12}\} - c_{12}] = 0. \end{aligned} \quad (7)$$

For equal initial link capacities, the delivery importance of link (1, 2) is zero when its

Figure 1.

capacity increases and -1 when its capacity decreases (use $-A$ in place of A); a similar analysis shows that the same is true for link $(2, 3)$. Thus, when the two links have the same capacity, they are of equal delivery importance. If the initial link capacities are equal, making one of them larger has no effect on the delivery function.

For a vector delivery function $\Psi = (\Psi_1, \dots, \Psi_v)$, the delivery importance of a network element $(i, j) \in \mathcal{N} \cup \mathcal{L}$ is the vector

$$\left(\frac{\partial \Psi_1}{\partial c_{ij}}, \dots, \frac{\partial \Psi_v}{\partial c_{ij}} \right), \quad (8)$$

when it exists. While vector delivery functions are important for many applications, the fact that the delivery importance is computed element by element, as in Equation (8), means that the delivery importance of a vector delivery function can be evaluated element by element, so we do not deal with vector delivery functions further in this article.

Because $\Psi: \Gamma \rightarrow \mathbf{R}$, $\Psi'(C)$ is a linear map from Γ into $\mathbf{R}$ for every C [20], and is therefore represented by a vector. To explicitly display this vector, it is convenient to order the network's incidence matrix as a vector by writing out its rows one after another as a row vector of length N^2 . Then the vector representing $\Psi'(C)$ is the vector of partial derivatives

$$\left(\frac{\partial \Psi}{\partial c_{11}}, \dots, \frac{\partial \Psi}{\partial c_{1N}}, \frac{\partial \Psi}{\partial c_{21}}, \dots, \frac{\partial \Psi}{\partial c_{2N}}, \right. \\ \left. \frac{\partial \Psi}{\partial c_{31}}, \dots, \frac{\partial \Psi}{\partial c_{NN}} \right),$$

where the (i, j) entry is zero if $(i, j) \notin \mathcal{L}$. Thus, we may write $\Omega_a(i, j; C_0)$ from Equation (2) as $\Omega_a(i, j; C_0) = \langle \Psi'(C_0), \mathbf{1}_{(i,j)} \rangle$ where $\mathbf{1}_{(i,j)}$ is a vector containing 1 in the (i, j) position and zeros elsewhere, and $\langle \cdot, \cdot \rangle$ represents the ordinary inner product in $\mathbf{R}^{N^2}$.

We may also consider the delivery importance of larger subsets of $\mathcal{N} \cup \mathcal{L}$. Let $\mathcal{M} \subset \mathcal{N} \cup \mathcal{L}$. Define $\mathbf{1}_{\mathcal{M}}$ to be the matrix whose (i, j) entry is given by $I\{(i, j) \in \mathcal{M}\}$, written as a row vector (see preceding paragraph) by concatenating the rows as a row vector of length N^2 . That is, $\mathbf{1}_{\mathcal{M}}$ contains a 1 in every position

corresponding to a network element belonging to $\mathcal{M}$ and a zero everywhere else. The direction $\mathbf{1}_{\mathcal{M}}$ represents increasing capacity of each of the network elements in $\mathcal{M}$. Then the delivery importance of $\mathcal{M}$ in the positive direction at C is defined as the derivative of the delivery function at C in the direction $\mathbf{1}_{\mathcal{M}}$, that is,

$$\Omega_+(\mathcal{M}; C) = \langle \Psi'(C), \mathbf{1}_{\mathcal{M}} \rangle. \quad (9)$$

The delivery importance of the empty set $\mathcal{M} = \emptyset$ is clearly zero.

Under suitable regularity conditions, the delivery importance may be computed by the Fréchet differential [21]

$$\langle \Psi'(C), \mathbf{1}_{\mathcal{M}} \rangle = \lim_{h \rightarrow 0^+} \frac{1}{h} [\Psi(C + h\mathbf{1}_{\mathcal{M}}) - \Psi(C)]. \quad (10)$$

We may consider delivery importance with any arrangement of signs in the matrix $\mathbf{1}_{\mathcal{M}}$, allowing for any combination of increases and decreases in network element capacity to be studied. In the definition of delivery importance, we have used the positive sign everywhere primarily for consistency with the classical definition of reliability importance [13]. For network resiliency (see the section titled "Network Resiliency"), we are primarily interested in what happens when capacities decrease, so in the definition of network resiliency we use delivery importance in the negative direction $-\mathbf{1}_{\mathcal{M}}$. It is also reasonable for some applications to consider delivery importance in other directions, which can be represented by matrices that contain $\pm I\{(i, j) \in \mathcal{M}\}$, where the 1 and -1 are chosen to represent growth or diminishment, respectively, of the capacity of the network element (i, j) . In this case, letting $A_{\mathcal{M}}$ stand for a matrix of this kind that contains $\pm I\{(i, j) \in \mathcal{M}\}$, we represent the delivery importance in the direction $A_{\mathcal{M}}$ by $\Omega_A(\mathcal{M}; C) = \langle \Psi'(C), A_{\mathcal{M}} \rangle$; in case all $-$ signs are chosen, we write $\Omega_-(\mathcal{M}; C) = \langle \Psi'(C), -\mathbf{1}_{\mathcal{M}} \rangle$.

Theorem 1. *For an almost everywhere differentiable scalar delivery function, the delivery importance in the positive direction at C_0 of a set $\mathcal{M}$ of network elements is equal*

to the sum of the partial derivatives of Ψ with respect to the capacities of the network elements in $\mathcal{M}$, evaluated at the nominal capacity matrix C_0

$$\Omega_+(\mathcal{M}; C_0) = \sum_{(i,j) \in \mathcal{M}} \left. \frac{\partial \Psi}{\partial c_{ij}} \right|_{C_0}, \quad (11)$$

when it exists.

Proof. This is a restatement of the inner product expression $\Omega_+(\mathcal{M}, C_0) = \langle \Psi'(C_0), \mathbf{1}_{\mathcal{M}} \rangle$.

Clearly, when $\mathcal{M}$ consists of a single element (i, j) , $\Omega_+(\mathcal{M}; C)$ reduces to $\Omega_1(i, j; C)$. Again, this definition is motivated by a one-term Taylor series expansion

$$\begin{aligned} \Psi(C_0 + hA) - \Psi(C_0) \\ = \sum_{(i,j) \in \mathcal{M}} h_{(i,j)} \left. \frac{\partial \Psi}{\partial c_{ij}} \right|_{C_0} a_{ij} + o(|h|), \end{aligned} \quad (12)$$

where h is now an $|\mathcal{M}|$ -vector; Equation (12) is derived by taking all elements of h to be equal (which amounts to modeling the postulate that the capacities of all network elements in $\mathcal{M}$ are changed at the same rate).

Example 1 (continued). We compute the delivery importance of the two links (1, 2) and (2, 3) together. In this example, this is the delivery importance of the entire network with respect to itself. We have

$$\Omega_+(\mathcal{H}; C_0) = I\{x < y\} + I\{y < x\} = I\{c_{12} \neq c_{23}\}, \quad (13)$$

which is 1 as long as $c_{12} \neq c_{23}$. Again when $c_{12} = c_{23}$, Equation (11) is not defined and we use the $|\mathcal{M}|$ -dimensional analog of Equation (1) instead, with $\mathbf{1}_{\mathcal{H}}$ as the 3×3 matrix containing 1 in the (1, 2) and (2, 3) positions and

zeros elsewhere

$$\begin{aligned} \Omega_+(\mathcal{H}; C_0) \\ = \lim_{h \rightarrow 0^+} \frac{1}{h} [\Psi(C_0 + h\mathbf{1}_{\mathcal{H}}) - \Psi(C_0)] \\ = \lim_{h \rightarrow 0^+} \frac{1}{h} [\min\{c_{12} + h, c_{12} + h\} - c_{12}] = 1. \end{aligned} \quad (14)$$

In this example, the delivery importance of the entire network with respect to itself is 1 regardless what C_0 might be.

Delivery Importance in Deterministic Capacitated Discrete Networks. In a capacitated discrete network, the capacity matrix has integer entries and the flows also take on only integer values. Derivatives of the delivery function are not defined in the classical sense. There are (at least) two alternatives. First, one may approximate the discrete network by a sequence of continuum networks for which the delivery importance is defined as in the section titled “Delivery Importance in Deterministic Capacitated Continuum Networks,” in this article, and then define the delivery importance for the discrete network as the limit of the delivery importance values in the approximating sequence of continuum networks, if the limit exists. The second alternative is to define delivery importance in a purely discrete fashion, as follows. Let $(\mathcal{H}, C, \Psi)$ be a deterministic capacitated discrete network with associated delivery function Ψ . The delivery importance at C of a network element (i, j) in the positive direction is given by

$$\Omega_+(i, j; C) = \Psi(C + \mathbf{1}_{ij}) - \Psi(C), \quad (15)$$

where $\mathbf{1}_{ij}$ is a matrix with a 1 in the i, j position and zeroes everywhere else. Similarly, for the delivery importance in the positive direction of a subset $\mathcal{M}$ of $\mathcal{N} \cup \mathcal{L}$, replace in Equation (15) the $\mathbf{1}_{ij}$ matrix by $\mathbf{1}_{\mathcal{M}}$. Unless otherwise noted, in this article we shall use the second alternative.

Delivery Importance in Stochastic Capacitated Networks. In a stochastic capacitated network, the network element capacities are

random variables. Consequently, the delivery function (we will assume it is measurable), delivery importance, and network resiliency in such a network are also random variables. As such, figures of merit for delivery importance and network resiliency may be constructed from moments and percentiles of these random variables. Thus, we speak of, for example, expected delivery importance as

$$\begin{aligned} E\Omega_+(\mathcal{M}; C) &= E\langle \Psi'(C), \mathbf{1}_{\mathcal{M}} \rangle \\ &= \int \langle \Psi'(C(\omega)), \mathbf{1}_{\mathcal{M}} \rangle P(d\omega), \end{aligned} \quad (16)$$

where the integration is over the sample space of the capacity random variables. In a similar fashion, we may employ the variance of delivery importance, the median delivery importance, the ninetieth percentile delivery importance, and so on.

Static Networks. In a static stochastic capacitated network, the capacities are fixed random quantities. These may represent the reliability of the network elements (in which case the range of the capacity function is $[0, 1]$ and the capacity represents the probability that the element is present in $\mathcal{H}$; see Example 2 for an illustration of this case), or the load-carrying capacity of the network element in a model in which the capacity is indeterminate for any reason (e.g., lack of precise information on the part of the network manager about the status of recently added elements to the network). It is required that the joint distribution of the network element capacities be known.

Dynamic Networks. In a dynamic stochastic capacitated network, the capacities are represented by stochastic processes with time as their parameter space. These networks model realistic networks having network element capacities that change at random because of, say, failures and repairs to parts of the network element. For example, the capacity of a network element in a deterministic capacitated network could be modeled with a continuous-time, discrete-state semi-Markov process. For dynamic stochastic capacitated networks,

the figures of merit for delivery importance, like those described in the section “Delivery Importance in Stochastic Capacitated Networks,” become functions of time as well.

Delivery Importance in Uncapacitated Networks

Delivery Importance in Deterministic Uncapacitated Networks In an uncapacitated network, proper functioning of the network is affected by only the presence or absence of a node or link, so “capacities” zero or one are assigned to each element of the network. The delivery function in such a network is usually one of the connectivity functions: 2-terminal, k -terminal, or all-terminal. Delivery importance in the positive direction, as defined in the section titled “Delivery Importance in Deterministic Capacitated Discrete Networks,” makes sense only for entries in the nominal capacity matrix where there are zeros. Similarly, delivery importance in the negative direction makes sense only for entries in the nominal capacity matrix where there are ones. For applications, probably the most useful delivery importance measure is delivery importance in the negative direction starting from a fully operational network, as in

$$\Omega_-(\mathcal{M}; H) = \Psi(H - \mathbf{1}_{\mathcal{M}}) - \Psi(H), \quad (17)$$

where H is the full incidence matrix (i.e., including the nodes) of $\mathcal{H}$. As usual, a vector delivery function is handled term by term.

Delivery Importance in Stochastic Uncapacitated Networks In a stochastic uncapacitated network, the basic setup is as in the section titled “Delivery Importance in Deterministic Uncapacitated Networks” with the additional feature that network elements are each assigned a number representing the probability that the element is in the graph or not. In case these probabilities are fixed, the network is static in the sense of the section titled “Static Networks”; in case they vary over time in some known fashion, the network is dynamic in the sense of the section titled “Dynamic Networks”. Moments, percentiles, and so on of the delivery function

and various delivery importance values can then be computed from these probabilities.

Example 1 (continued). Consider again the network shown in Fig. 1, now with unreliable links. We set $p_{ij} = EI\{(i,j) \in \mathcal{H}\} = P\{(i,j) \in \mathcal{H}\}$, $i, j = 1, 2, 3$. For economy's sake, we assume $p_{11} = p_{22} = p_{33} = 1$, and $p_{13} = p_{31} = 0$ because the network does not contain a link from node 1 to node 3. $p_{21} = p_{32} = 0$, because the network is directed, and we assume that the remaining probabilities are neither zero nor one. Then the expected value of the delivery function is $E\Psi = p_{12} + p_{23} - p_{12}p_{23}$. The expected delivery importance in the negative direction of the links are $E\Omega_-(1, 2; H) = E\Omega_-(2, 3; H) = p_{12}p_{23} - p_{12} - p_{23}$.

NETWORK RESILIENCY

Deterministic Networks

The first essential idea of network resiliency is that a resilient network is one that has few subsets that have large delivery importance, or conversely most subsets have small delivery importance. This expresses the idea that removal of, or decrease in capacity of, most network elements has little effect on the delivery function of the network if the network is resilient. The remainder of this section is devoted to formalizing this idea in the context of the framework we have created for delivery functions and delivery importance.

In the most general formulation, we define network resiliency to be the proportion of subsets of the network whose absolute delivery importance values in the negative direction do not exceed a given value. Formally, this is

$$\rho(\mathcal{H}, C_0; x) = \frac{1}{2^{|\mathcal{N} \cup \mathcal{L}|}} \sum_{\mathcal{M} \subset \mathcal{N} \cup \mathcal{L}} I\{|\Omega_-(\mathcal{M}; C_0)| \leq x\},$$

$$x \geq 0, \quad (18)$$

a nondecreasing function. A resilient network is one for which this function remains close to zero, only increasing sharply to 1 for large values of x .

The computation of $\rho(\mathcal{H}, C_0; x)$ by Equation (18) can be daunting for even modest-sized networks, and in practical cases there is usually little reason to consider very large subsets of $\mathcal{N} \cup \mathcal{L}$ unless events that disturb all but a small number of network elements are common.¹ Therefore, there is interest in restricted network resiliency figures of merit based on only certain subsets of $\mathcal{N} \cup \mathcal{L}$, especially if study of only a particular subset is of interest or if it is possible to identify in advance subsets that have less influence on the delivery function. It is useful to denote restricted network resiliency, say with respect to a subset Z of $\mathcal{N} \cup \mathcal{L}$, by $\rho(\mathcal{H}, Z, C_0; x)$. Then we would have

$$\rho(\mathcal{H}, Z, C_0; x) = \frac{1}{|Z|} \sum_{\mathcal{M} \subset Z} I\{|\Omega_-(\mathcal{M}; C_0)| \leq x\},$$

$$x \geq 0. \quad (19)$$

For instance, we may be interested in the resiliency of the network when disruptions to only single network elements are considered; we call this the 1-resiliency of the network and compute it with Z equal to the set of all single-element subsets of $\mathcal{N} \cup \mathcal{L}$. More generally, we may consider the k -resiliency of the network

$$\rho_k(\mathcal{H}, C_0; x) = \left(\binom{|\mathcal{N} \cup \mathcal{L}|}{k} \right)^{-1} \sum_{\mathcal{M} \subset Z_k} I\{|\Omega_-(\mathcal{M}; C_0)| \leq x\},$$

$$x \geq 0, \quad (20)$$

where Z_k represents the set of all subsets of $\mathcal{N} \cup \mathcal{L}$ that contain k elements.

In applications, these expressions may be difficult to work with because they are functions, rather than scalars, so comparisons between different networks are not always possible.² Also, significant computation might be required to evaluate them. Thus, there is interest in simpler network

¹Certain kinds of cyber attacks can disturb large subsets of a network at once.

²A partial order, similar to stochastic order, can be developed on the basis of these expressions.

resiliency characterizations; the section titled “Figures of Merit for Network Resiliency” is devoted to some explorations of these ideas.

Stochastic Networks

In a stochastic network, $\Omega_-(\mathcal{M}, C_0)$ is a random variable, and the expected value of Equation (18) contains its distribution:

$$\begin{aligned} E\rho(\mathcal{H}, C_0; x) &= \frac{1}{2^{|\mathcal{N} \cup \mathcal{L}|}} \sum_{\mathcal{M} \subset \mathcal{N} \cup \mathcal{L}} P\{|\Omega_-(\mathcal{M}; C_0)| \leq x\}, \\ x &\geq 0. \end{aligned} \quad (21)$$

Similar expressions for the expected values of Equations (19) and (20) may be developed.

FIGURES OF MERIT FOR NETWORK RESILIENCY

Deterministic Networks

We use the concepts of delivery function and delivery importance of (sets of) network elements to define network resiliency in quantitative terms. Note that because delivery importance is keyed to a specific delivery function and nominal capacity matrix, network resiliency is specifically defined only with respect to the chosen delivery function and nominal capacity matrix.

Definition. For a deterministic capacitated network $(\mathcal{H}, C, \Psi)$ with associated delivery function, *scalar network resiliency* $\rho^*(\mathcal{H}; C_0)$ at a nominal capacity matrix C_0 is defined as the largest of the absolute delivery importance values in the negative direction (capacities decrease) across all subsets of the elements (nodes and links) in the network:

$$\rho^*(\mathcal{H}; C_0) = \max_{\mathcal{M} \subset \mathcal{N} \cup \mathcal{L}} |\Omega_-(\mathcal{M}; C_0)| \quad (22)$$

The largest delivery importance value indicates the subset of $\mathcal{N} \cup \mathcal{L}$ to which the delivery function is most sensitive or that has the largest “lever effect” on the delivery function. Note that smaller is better in

Equation (22) because we want a resilient network to be one that is insensitive to changes in its network elements, that is, one that makes the right-hand side of Equation (22) small. That is, we say a network is resilient if $\rho^*(\mathcal{H}, C_0)$ is small. Computation of network resiliency for a scalar delivery function by this definition requires only $|\mathcal{N} \cup \mathcal{L}|$ delivery importance computations and at most $|\mathcal{N} \cup \mathcal{L}| \cdot 2^{|\mathcal{N} \cup \mathcal{L}|}$ additions because the delivery importance for a subset $\mathcal{M}$ of $\mathcal{N} \cup \mathcal{L}$ is obtained by summing the delivery importance values of each of the individual network elements contained in $\mathcal{M}$; see Theorem 1.

Clearly, the same kinds of restricted scalar network resiliency values as, for example, in Equations (19) and (20) are possible here as well, unless otherwise specified, further discussion of scalar network resiliency in this article refers to the full definition (22).

Scalar network resiliency is not an absolute scale quantity but it induces a partial order on the set of networks with associated delivery functions. Therefore, it is mainly useful for making comparisons in a set of networks rather than for associating a meaningful number with a fixed network.

Stochastic Networks

In a stochastic network, scalar network resiliency (Eq. 22) is a random variable, and may be a function of time also if the network is dynamic. As before, figures of merit for network resiliency are constructed on the basis of moments and percentiles of the network resiliency random variable. If the network is dynamic, these figures of merit will be functions of time as well.

METRICS FOR NETWORK RESILIENCY

A figure of merit, in the sense used in the section “Figures of Merit for Network Resiliency,” represents an “ideal” description of some phenomenon in a model. A figure of merit is computed from assumptions and a model structure and represents a quantitative description of some inherent quality of the phenomenon under study. For

example, “maintainability” is the inherent ability of a system to be repaired and restored to service when maintenance is conducted by personnel using specified skill levels and prescribed procedures and resources [22]. Many figures of merit are associated with maintainability, such as maintenance downtime and logistic delay. These may be developed from a model of the system under study (e.g., an alternating renewal process) together with assumptions about location of spares, skill of repair personnel, and so on. When the system is in operation, data may be collected relating to these figures of merit, and estimators of the population value of the figure of merit may be constructed from these data. These estimators are called *metrics*. For example, during system operation we may record the amount of time the system is out of service for maintenance reasons (preventive, corrective, opportunistic, etc.) and these data may be used to estimate the mean and variance of the maintenance downtime across a population of similar systems. For further discussion of figures of merit and metrics, see [11].

In the case of network resiliency, we have introduced several figures of merit in the section titled “Figures of Merit for Network Resiliency.” Metrics may be constructed for these from data relating to delivery importance. For instance, we may record the change in the delivery function between two specified network nodes when there is a failure of one element somewhere in the network. Aggregation of these data would permit estimation of the 1-resiliency of the network. Clearly, many details have been omitted from this description, and several questions would need to be settled before satisfactory metrics for network resiliency could be developed. We reserve detailed discussion of metrics for network resiliency for further treatment elsewhere.

THREE EXAMPLES OF DELIVERY FUNCTIONS

Connectivity

Consider a network $(\mathcal{H}; C)$ in which all capacities are either zero or one (i.e., $c_{ij} = I\{(i, j) \in \mathcal{L}\}$). Associated delivery functions consistent

Figure 2.

with this example are 2-terminal, k -terminal ($2 < k < N$), or all-terminal connectivity of $(\mathcal{H}; C)$. We define the connectivity of some subset of nodes in the network to be 1 if there are paths connecting all the nodes in the subset to one another (i.e., every node in the subset can be reached from other node in the subset), and 0 otherwise. Note that some authors define connectivity to be the probability that paths connecting the nodes exist when the probability that a network element is in the graph is given; this is the expected connectivity in our formulation and is studied in the next section. Computation of all-terminal connectivity in the latter sense (i.e., all-terminal reliability) using a reduction algorithm is reviewed in Ref. 23.

The following simple example conveys the essential points of network resiliency involving connectivity.

Example 2. Consider the simple three-terminal directed network H shown in Fig. 2.

The full incidence matrix of $\mathcal{H}$ is

$$H = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 1 \\ 0 & 0 & 1 \end{pmatrix} \quad (23)$$

and the delivery function Ψ for this example is the two-terminal connectivity for terminals 1 and 3. That is, $\Psi = 1$ if there is a path connecting node 1 to node 3 and is zero otherwise. The capacity of element $(i, j) \in \mathcal{H}$ is $c_{ij} = I\{(i, j) \in \mathcal{H}\}$, $i, j = 1, 2, 3$. For economy's sake, let us ignore the contribution of the nodes; it is clear enough how to incorporate their contribution should it be desirable. Then

$$\begin{aligned} \Psi &= I\{(1, 3) \in \mathcal{H}\} \cup [(1, 2) \in \mathcal{H}] \cap [(2, 3) \in \mathcal{H}] \\ &= c_{13} + c_{12}c_{23} - c_{12}c_{23}c_{13}. \end{aligned} \quad (24)$$

The delivery importance of link (1,3) in the negative direction is

$$\begin{aligned}
\Omega_-((1,3); C) &= \Psi(C - \mathbf{1}_{(1,3)}) - \Psi(C) \\
&= c_{12}c_{23} - [c_{13} + c_{12}c_{23} - c_{12}c_{23}c_{13}] \\
&= c_{12}c_{23}c_{13} - c_{13}. \tag{25}
\end{aligned}$$

Table 1 gives the delivery importance values for each nonempty subset of $\mathcal{H}$.

Choose the network's incidence matrix H (Eq. 23) as a nominal capacity matrix. This represents a situation in which all the network's elements are initially in an operating condition. Then, with respect to this nominal capacity matrix, the delivery importance values from Equation (17) are $\Omega_-(\mathcal{M}, H) = 0$ for $\mathcal{M} = \{(1,3)\}, \{(2,3)\}, \{(1,2)\}$, and $\{(1,2) \cup (2,3)\}$, and $\Omega_-(\mathcal{M}, H) = -1$ for $\mathcal{M} = \{(1,3) \cup (2,3)\}, \{(1,3) \cup (1,2)\}$, and $\mathcal{H}$. The network resiliency function (18) at the nominal capacity matrix H is a right-continuous step function with jumps at 0 and 1; the height of the jump at zero is 5/8 and the height of the jump at 1 is 3/8.

Reliability

Consider a network $(\mathcal{H}; C)$ in which, instead of all capacities being zero or one (i.e., $c_{ij} = I\{(i,j) \in \mathcal{L}\}$ as before), we postulate that $P\{c_{ij} = 1\} = p_{ij}$ for all $(i,j) \in \mathcal{L}$. Such a model represents a network in which network elements are unreliable, that is, may fail to function in the network with some given probability. Suitable delivery functions in this case include 2-terminal, k -terminal, and all-terminal reliability, defined as the probability that there are working paths

Table 1. Delivery Importance Values for Example 2

Subset of $\mathcal{H}$	Delivery Importance
$\{(1,3)\}$	$c_{12}c_{23}c_{13} - c_{13}$
$\{(2,3)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23}$
$\{(1,2)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23}$
$\{(1,2) \cup (2,3)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23}$
$\{(1,3) \cup (2,3)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23} - c_{13} = -\Psi(\mathcal{H})$
$\{(1,3) \cup (1,2)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23} - c_{13}$
$\mathcal{H}$	$c_{12}c_{23}c_{13} - c_{12}c_{23} - c_{13}$

connecting a given subset of the nodes of the network (two nodes, k nodes, or all nodes, as appropriate). We continue with Example 2 to illustrate network resiliency in this case.

Example 2 (continued). The capacity of element $P\{c_{ij} = 1\} = p_{ij}$ for all $(i,j) \in \mathcal{L}$. We assume the network elements are mutually stochastically independent. For economy's sake, we again ignore the contribution of the nodes. Table 2 gives the delivery importance and expected delivery importance values for each nonempty subset of $\mathcal{H}$.

As before, when the nominal capacity matrix is H , the delivery importance values from Equation (17) are $\Omega_-(\mathcal{M}, H) = 0$ for $\mathcal{M} = \{(1,3)\}, \{(2,3)\}, \{(1,2)\}$, and $\{(1,2) \cup (2,3)\}$, and $\Omega_-(\mathcal{M}, H) = -1$ for $\mathcal{M} = \{(1,3) \cup (2,3)\}, \{(1,3) \cup (1,2)\}$, and $\mathcal{H}$. The network resiliency function is zero with probability $p_\infty = P[\{(1,3) \notin \mathcal{H}\} \cup \{(2,3) \notin \mathcal{H}\} \cup \{(1,2) \notin \mathcal{H}\} \cup \{(\{(1,2) \notin \mathcal{H}\} \cap \{(2,3) \notin \mathcal{H}\})\}]$ and is -1 with probability $1 - p_\infty$. The expected network resiliency is $p_\infty - 1$.

Stochastic Flow

Consider a continuum network that delivers, for example, oil from node A to node B. The node and link capacities in this network are modeled as continuous-time Gaussian processes $\{X_{ij}(t) : t \geq 0\}$ having almost surely continuously differentiable sample paths [25, Section 4.3], indicating the change in capacity of the network elements from time to time due to failures and repairs, degradation, corrosion, or similar phenomena. The delivery function is the volume of oil delivered from node A to node B over a stated interval of time $[0, T]$, $T < \infty$. The capacity of a network element is the maximum flow (volume per unit time) permitted in that network element. Set $X(t) = (X_{ij}(t) : i, j = 1, \dots, N)$ and $C_0 = X(0)$. Let $\varphi(t)$ denote the flow in the network at time t assuming a maximum-flow scenario [18], and $\varphi_{AB}(t)$ denote the flow from node A to node B under this scenario. Then the delivery function consistent with this model is

$$\Psi(X; T) = \int_0^T \varphi_{AB}(t) dt. \tag{26}$$

Then the delivery importance of a subset $\mathcal{M}$ of network elements is given by the random variable

$$\Omega_-(\mathcal{M}, X) = - \sum_{(i,j) \in \mathcal{M}} \int_0^T \frac{\partial \varphi_{AB}}{\partial x_{ij}}(t) dt. \quad (27)$$

If, as is usually reasonable to assume, the flow φ_{AB} is a nondecreasing function of the network element capacities, then $\Omega_-(\mathcal{M}, X) \leq 0$, and the scalar network resiliency with respect to the given delivery function is

$$\rho^*(\mathcal{H}; X) = \max_{\mathcal{M} \subset \mathcal{N} \cup \mathcal{L}} \sum_{(i,j) \in \mathcal{M}} \int_0^T \frac{\partial \varphi_{AB}}{\partial x_{ij}}(t) dt. \quad (28)$$

Assuming the processes $\{X_{ij}(t)\}$ are mutually stochastically independent, we obtain

$$P\{\Psi(X; T) > V\} = \int_0^\infty \cdots \int_0^\infty P \left\{ \int_0^T \varphi_{AB}(t) dt > V | X_{ij}(t) = x_{ij} \right\} dp \{X_{ij}(t) \leq x_{ij}\} \quad (29)$$

and then the methods of Ramirez-Marquez *et al.* [25, 26] may be used to calculate the conditional probabilities in Equation (29), where V is a desired volume of oil.

NETWORK RESILIENCY OPTIMIZATION

In creation of real networks, it is in many cases clearly of interest to be able to optimize network resiliency. The framework outlined above enables the formulation of an optimization problem for network resiliency in a capacitated network when a cost function for provisioning specified node and link capacity

is known. $\gamma(C)$ denotes the cost of deploying a network whose capacity matrix is C .

Solving the following optimization problem leads to a network designed for maximum scalar resiliency:

$$\text{Maximize } \rho^*(\mathcal{H}; C) \text{ subject to } \gamma(C) \leq \gamma_0,$$

where γ_0 is the allowable maximum cost. The design variables that may be manipulated to complete the optimization include the network topology and the capacity matrix.

DESIGN FOR NETWORK RESILIENCY PRINCIPLES AND PRACTICES

To develop a good catalog of design for network resiliency principles and practices requires a extensive experience in solving network resiliency optimization problems and applying the solutions in real networks. Because this is a rather new area, not much such experience exists. Nonetheless, some general principles can be stated by appealing to properties of the delivery function, graph structure, and so on. This section discusses some specific actions that can be taken by network designers to increase network resiliency. We evaluate the efficacy of design actions by determining whether the scalar network resiliency (see the section titled “Figures of Merit for Network Resiliency”) decreases (smaller is better) as a result of the action. In a capacitated network, it is reasonable to assume that the delivery function is a nondecreasing function of the capacity matrix (i.e., an increase in one or more entries in the capacity matrix causes the delivery function to increase or remain the same).

Table 2. Expected Delivery Importance Values for Example 2

Subset of $\mathcal{H}$	Delivery Importance	Expected Delivery Importance
$\{(1, 3)\}$	$c_{12}c_{23}c_{13} - c_{13}$	$p_{12}p_{23}p_{13} - p_{13}$
$\{(2, 3)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23}$	$p_{12}p_{23}p_{13} - p_{12}p_{23}$
$\{(1, 2)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23}$	$p_{12}p_{23}p_{13} - p_{12}p_{23}$
$\{(1, 2) \cup (2, 3)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23}$	$p_{12}p_{23}p_{13} - p_{12}p_{23}$
$\{(1, 3) \cup (2, 3)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23} - c_{13} = -\Psi(\mathcal{H})$	$p_{12}p_{23}p_{13} - p_{12}p_{23} - p_{13}$
$\{(1, 3) \cup (1, 2)\}$	$c_{12}c_{23}c_{13} - c_{12}c_{23} - c_{13}$	$p_{12}p_{23}p_{13} - p_{12}p_{23} - p_{13}$
$\mathcal{H}$	$c_{12}c_{23}c_{13} - c_{12}c_{23} - c_{13}$	$p_{12}p_{23}p_{13} - p_{12}p_{23} - p_{13}$

Systematic Overprovisioning

In a capacitated network, one of the most common ways of promoting greater network resiliency is by overprovisioning, that is, making the capacities of the network elements larger than would be required to just meet stated service reliability objectives. For example, in early telecommunications networks, certain trunk groups (collections of circuits connecting two switching offices) were designed to block no more than 1% of the offered traffic during the busy hour [27] (i.e., no more than 1% of the arriving calls will find all trunks already occupied). For an offered load of 100 Erlangs (one Erlang is one call arrival per mean holding time; for example, if the mean holding time of a call is 6 min, one Erlang of traffic constitutes a Poisson process whose arrival rate is 10 calls per hour), the number of trunks required to meet this goal is 117. To overprovision, a larger number of trunks, say 144, would be installed, and then, with the same 100 Erlang load, the blocking probability would be reduced to 6.7×10^{-6} . This same idea can be replicated throughout a capacitated network; while the computation of delivery importance and network resiliency might be more complicated, the basic idea of overprovisioning is the same as it is in the simple circuit-switched telecommunications trunk group example.

If the delivery function is a nondecreasing function of the capacity matrix, then overprovisioning (i.e., providing more capacity on a route than is required to just meet a stated service objective for that route) leads to increased scalar network resiliency with respect to a nominal capacity matrix representing exact provisioning because all delivery importance values are nonnegative. Whether overprovisioning is an efficient means of promoting network resiliency is another matter that is beyond the scope of this article.

Failure Decoupling

When a network's associated delivery function is nondecreasing, the larger the number of network elements that experience malfunction (or decrease in capacity), the larger

the decrease in the value of the delivery function. It follows that network resiliency will be improved if there can be employed schemes to prevent failures in network elements from cascading or propagating to other network elements. We refer to such schemes broadly as *failure decoupling*. Failure to properly decouple network elements may lead to widespread network element outages and greatly impaired delivery functions. For example, in January 1990, the AT&T Signaling System 7 (SS7) transaction management data network suffered an extensive outage because a software failure in one of the SS7 switching nodes led to a situation in which nodes connected to the failed node went out of service because they received improper status information from the failed node. The failures cascaded in less than 10 min to over 100 SS7 nodes, resulting in a 9-h outage that affected 60,000 customers and cost AT&T approximately \$60 million in lost revenue [28]. Had flawed status information not been passed on to neighboring nodes, the scope of the outage would have been greatly reduced.

Measures that can be taken as part of network design to minimize the possibility of propagating a network element failure to other network elements include implementation of a supervisory network monitoring system such as that employed in undersea cable telecommunications systems [29], implementation of a "heartbeat" status monitoring and communication system [30], and implementation of an alarm capability to notify network operations managers of network element failure in real time.

The latter scheme points toward the role of network management and control in containing the propagation of network element failures. As many large network operations implement a centralized network monitoring and intervention capability (e.g., the AT&T Global Network Operations Center [31]), we discuss this idea in more detail below.

Reactive Control. Reactive control refers to the actions that are taken by network managers (human or automatic) in response to a disruption in the network. A disruption is by definition something that interferes with the satisfactory functioning of one or more

network elements, leading to a degradation in the performance of the network's functions, and (with the assumption about monotonicity of the delivery function given in the section titled "Design for Network Resiliency Principles and Practices") is reflected in a decrease in the value of the network's delivery function. Disruptions may be routine and manageable, or they may be sudden and unexpected.

Routine disruptions are those that can be anticipated and planned for in advance of their occurrence. For example, the chronic process of failures and repairs that takes place in all network elements can be thought of as routine disruption because network managers know that these will occur even if it is not possible to predict exactly when and where they will occur. In a sense, they can be predicted statistically; indeed, about 3% of the routers in the Internet are out of service at any time because of routine failures. Consequently, managers can anticipate these failures and put in place operational tactics that mitigate their effects. Indeed, the TCP/IP network protocol is specifically designed to automatically route around failed routers and/or links. This, together with the hub-and-spoke topology of the Internet, allows us to conjecture that the resiliency (Eq. 22) of the Internet has a logistic shape: it remains small for increasing numbers of failed routers and/or links until a threshold is reached, and then it increases abruptly as the number of failed routers and/or links continues to increase. An example of an automatic reactive control is given by the AT&T FAS-TAR [32] system created to enable automatic rerouting around failed DS3 transport links in the public switched telephone network.

Sudden and unpredictable disruptions are due to events like natural disasters and deliberate attacks. These are usually large in scope and extended in time. In circuit-switched telecommunications networks, long experience helped codify a set of network management principles that were employed to mitigate the effects of losing large portions of a network due to, for example, earthquakes, floods, and other natural disasters. That technology had advanced to a point that it was encapsulated in an expert system [33].

Smart Networks. There has been a recent trend toward exploiting information technology for improved management of network operations. The ability to acquire and archive large quantities of data makes it possible to obtain a richer picture of network operations and to run analyses in real time that allow more intelligent decisions to be made regarding management of a network for continued satisfactory operation of a delivery function when changes to the network occur. Two approaches have been common in recent literature: a top-down approach and a bottom-up approach. We briefly discuss each of these in turn.

Macro-Smarts. A macro-smart network is one that uses global, or network-wide, data to inform network managers about current status and potential evolution of network operation. Internet protocol (IP) telecommunications networks encapsulate this sort of network management by the way routing tables change in response to failed links and routers. Updating routing tables in (close to) real time allows an IP network's open-shortest-path-first (OSPF) routing scheme to automatically bypass failed routers and links. That is, a router in an IP network will never even try to send a packet over a failed link or to a failed router when its routing tables are up to date with current information on the location of failures in the network.

Micro-Smarts. A micro-smart network is one that uses local data to inform network managers about current status and potential evolution of network operation. For example, electric power networks are beginning to use so-called *smart metering* to enable the network operator to control the flow of power to specific end users at specific times so that focused overloads, such as might occur because of heavy air-conditioning demands on hot summer days, can be avoided for the benefit of a larger number of users who will not experience a blackout that might otherwise occur due to the overload. This is an example of an active intervention that is possible because information that was not previously available at the end user level of

detail is now made visible by smart metering. It is anticipated that the smart grid market will reach \$200 billion by 2015 [34].

NETWORK INTERDICTION

Network interdiction can be considered as the study of methods for making a network *less* resilient. Network interdiction studies aim to find the network element, or set of network elements, that maximally disrupts the operation of the network. In the language introduced here, maximal disruption to the operation of the network means the largest decrease in the network's delivery function. The set $\mathcal{M}_0$ of $\mathcal{N} \cup \mathcal{L}$ that realizes the scalar network resiliency value, $\rho^*(\mathcal{H}; C) = |\Omega_-(\mathcal{M}_0; C)|$, is the subset of network elements whose removal from the network decreases the delivery function (when the capacity matrix is C) more than the removal of any other subset and therefore is the set sought by network interdiction.

Network interdiction studies began in a military context; for some examples see Refs 36 and 37. Other network interdiction studies include Refs 37–40.

CONCLUSION

This article presents a quantitative framework for studying network resiliency. The concept of network resiliency has gained increased importance recently as executives and managers realize the possibilities for disruption of critical network infrastructures because of not only natural disasters but also malicious actors and deliberate attacks. We introduce the concepts of a network with associated delivery function and of delivery importance to enable quantitative characterization of network resiliency. We discuss the application to discrete and continuum capacitated and uncapacitated networks, both deterministic and stochastic. Three examples of delivery functions are provided, and we briefly summarize how to solve the network interdiction using the proposed network resiliency framework.

DETERMINISTIC DYNAMIC PROGRAMMING (DP) MODELS

DAVID K. SMITH
Mathematical Sciences in
SECaM, University of Exeter,
Devon, UK

In deterministic dynamic programming (DP) models, the transition between states following a decision is completely predictable. Knowledge of the triple “stage, state, decision” allows the modeler to know the subsequent state and the single-stage cost associated with the decision and transition. This knowledge makes the recurrence relation straightforward, as the cost of a decision is the appropriate combination of single-stage cost and the cost of the subsequent optimal policy. The optimal policy for the current state and stage can then be found by finding the best cost, taken over all possible decisions.

As a result, deterministic DP models may appear easy to solve. And in general they are. Deterministic models are normally simpler than models of a similar size where there are stochastic aspects. This does not make the models irrelevant or trivial. As has already been discussed, DP models of all kinds are not “black boxes.” There are many varieties of deterministic DP problems.

It is not possible to describe here every area of application of deterministic DP. Annually, many hundreds of research papers describe new areas, or refinements of old ones. Frequently these are based on the DP premise that a given problem can be broken into a sequence of similar, smaller versions of itself, using the principle of recursion. Computer scientists have recognized this premise in several problems of search and storage of strings of information. A search in a long string may identify a crucial point in that string, and that point defines two shorter (but essentially similar) strings to be searched. The problem known as the *longest common subsequence problem* compares

two such strings and tries to find those parts that are most like each other [1]. The problem has been used to store the changes to computer files (instead of storing two copies of a large file, store one copy and use DP to record the changes) and computer displays. Biologists studying DNA use DP to match subsequences of DNA from different sources, to find similarities between different organisms. Economists and meteorologists have used DP to match time series in order to identify periods of time with similar conditions, whether concerned with the stock market or the weather. Many areas of pattern recognition use DP to identify similarities [2].

As will be described below, DP principles are used in some everyday electronics. Matching of sequences of information by DP is part of some voice recognition systems, which try to match the inflexion of a caller saying (e.g.) a single digit with recorded versions of people speaking each of the 10 digits [3].

Also within the realm of computer science is the problem of matrix multiplication. To multiply two matrices together it is necessary to perform multiplications and additions for every cell in the final matrix. The larger this is, the greater the amount of work. Multiplying three or more matrices will produce intermediate answers. Using DP, one can decide on the order of calculating these intermediate results, so as to minimize the number of numerical operations that are needed [4].

The classic “traveling salesperson problem,” which requires the identification of a constrained optimal route through several nodes (cities) can be formulated as a DP problem. The size of practical examples of this problem means that the formulation is a tool for searching for the solution, and not a solution method in itself.

The formulations of these problems are characterized by the method of calculating the single-stage costs, the form of the transition, and the nature of the recurrence relation. In the sections that follow, some well-known examples of the varieties of these forms will be described. In some cases,

the DP model is useful for thinking about the problem (as mentioned in the preceding paragraph about the traveling salesperson problem) and there are alternative computational techniques available. Most of the examples below were developed by Bellman and can be found in his books, for example [5].

THE STAGECOACH PROBLEM (SHORTEST PATH)

Over the last few years, the use of satellite navigation systems and route-finding computer programs (or web sites) has increased immensely. The logic behind such systems is based on a basic DP model. This model is based on a simple piece of reasoning, although in practice the implementation may be complex. Suppose the traveler wishes to find the best (meaning least distance) route from place A to place B. Then the journey will start with a journey to place C, different from A. Place C could be one of several possible places, $C_1, C_2, C_3, \dots, C_r$. These can be regarded as a set of places C_i , where i varies from 1 to r . The traveler knows the distance from A to each of these places. Bellman's principles show that following the selection of a place C_i , the traveler must follow the best route from C_i to B. So the distance of interest for the traveler from A to B via C_1 is the distance from A to C_1 added to the length of the best route from C_1 to B. Similarly for each of the possible places $C_1, C_2, C_3, \dots, C_r$. Given these r possible routes, and their distances, the traveler's policy is to choose the shortest route. This assumes that the traveler has already calculated the length of the best route from each of the possible places $C_1, C_2, C_3, \dots, C_r$. This can be done in the same way, reasoning that after C_i there will be a next place and this can be selected to minimize the distance from C_i to B. That journey will require one fewer stage than the journey from A, and so the calculation will be simpler. Repeatedly considering the next place will eventually lead the traveler to consider places for which the best place to go to next is place B, the chosen destination.

Different applications will need different sets of places. The options for a motorist,

a cyclist, or a walker will be road junctions. Users of public transport may consider places where it is possible to change between forms of public transport. For a long journey, there may be thousands of possible places to consider.

So, in words, the value of distance from A to B via C_i equals distance from A to C_i plus optimal distance from C_i to B. The optimal distance from A to B is found by taking the minimum over all possible C_i of (distance from A to B via C_i).

Considering this in DP terms, the states and decisions have been identified, along with the recurrence relation in words. Stages have not yet been identified. One way of identifying stages is to define place A as stage 1, and make place B as stage M, where M is some large number, say 999. All the possible places C_i become states for stage 2, all the places that can be reached from any of the C_i become states of stage 3, and so on. The list of states is a list of those places that might be visited on a journey from A to B. Of course, place B is in the list; it may appear before stage M, but in that case the distance from B to B is 0—the optimal decision when state B is reached is to stay put.

The formal statement of the mathematical model is as follows:

$$f_n(s) = \min_x (d(s, x) + f_{(n+1)}(x)),$$

where s represents the state at stage n , the variable x identifies the possible states that can be considered at stage $(n + 1)$ (with the decision being made to go to x) and $d(s, x)$ is the distance from s to x , the single-stage cost. The value of the function $f_n(s)$ represents the shortest distance from s to the destination B. The “boundary conditions” are that any distance from B to itself has value 0. To calculate the value of $f_n(s)$ for other states, one evaluates the function for those places where there is a direct link from s to B, then uses these values to find the function value for places where there is one intermediate stop, and so on back to place A and $f_1(A)$.

This model is often called a *stagecoach model* because of the explanatory model devised by Harvey Wagner in the 1960s. He imagined that the decision maker was

a traveler in the nineteenth century, in the United States of America. The traveler needed to make a journey from one state to another, some distance away. To make this journey, the traveler would go by stagecoach from one state to an adjacent one. In each state, it would be necessary to decide which state to visit next. Instead of describing the single-stage cost as the distance, Wagner imagined that the traveler bought some form of travel insurance and the cost of this was the value used in $d(s, x)$ in the expression above. The combination of the insurances for each decision yielded an insurance policy, which, of course, could be described as the optimal policy.

It is worth noting that all deterministic DP problems can be rearranged to be like the stagecoach problem. Because a decision is deterministic, it can be represented as the transition between two states, with an associated cost. In spite of this, it is normal to consider variations as separate ways of formulating problems, as explained in the later part of this article.

THE KNAPSACK PROBLEM

Another classic deterministic DP problem is the knapsack problem. This model is concerned with maximizing an objective, usually considered to be the value of the “knapsack.” The decision is about which items to pack, from a large set of items, which are too numerous and bulky for all to be packed in the limited space (The name “knapsack” has stuck with this problem, even though the model has wider application.). Suppose that there are N items that can be packed in the limited space. Each item i has a value V_i and weight W_i , and the need is to select whether or not to pack each item and not exceed a maximum total weight, MAXW. The total value of the load is the sum of the values of the items that are packed.

DP imagines that the decisions about what to pack can be made sequentially. At the beginning, no decisions have been made and there is a possible weight MAXW available. Then the decision is made whether or not to pack item number 1. After that, there will

be either weight MAXW or weight MAXW - W_1 available for packing. The decision about item 1 has happened, and the problem progresses to a decision about item 2. It will be necessary to consider what to do with each possible value of the remaining weight available. Once this has been done, the focus moves to item number 3 and so on. Considered as a DP model, the stages will be the number of decisions that have been made, starting from 0 and ending at N . The state of the formulation will be the weight that is available (in the hypothetical knapsack) for packing. The single-stage cost is the value of the decision, which is 0 if an item is not selected, and the worth of the item if it is selected. The objective function will be the total value of a knapsack packed optimally with the remaining items, given the weight available.

This leads to a recurrence relation

$$f_n(w) = \max(0 + f_{n+1}(w), V_n + f_{n+1}(w - W_n)),$$

(provided that w is at least as large as W_n) where w is the weight available after n items have been considered. The two expressions on the right-hand side represent the two possible situations that could occur after the decision. The first corresponds to not packing item n , the second to packing it, thereby gaining the value and losing the capacity. The value of $f_{N+1}(w)$ is 0 for any value of w , showing that there is no value in any space that is left when $N + 1$ decisions have been made.

As an example, suppose there are three items, with weights 5, 4, and 2 units, and MAXW is 6. The three items have values 25, 18, and 8 respectively.

Then $f_4(w) = 0$ for all w .

From the recurrence relation, $f_3(w) = \max(f_4(w), 8 + f_4(w - 2))$ and so $f_3(0) = 0$, $f_3(1) = 0$, and $f_3(w) = 8$ when $w \leq 2$. This means, obviously, that when w is 2 or more, the best thing to do is to pack one item of type 3.

Again, $f_2(w) = \max(f_3(w), 18 + f_3(w - 4))$ and so $f_2(0) = f_2(1) = 0$, $f_2(2) = f_2(3) = 8$, $f_2(4) = f_2(5) = 18$, and $f_2(6) = 26$. This means that when there is insufficient space for an item of type 2, the best thing is to ignore it

and follow the optimal policy for the next stage; when there is space for an item of type 2, then pack it, and if there is enough space left over, then pack an item of type 3.

Finally, $f_1(6) = \max(f_2(6), 25 + f_2(1)) = \max(26, 25 + 0) = 26$ corresponding to packing items 2 and 3, even though these were not the most valuable items, nor did they give the largest value per unit weight.

In this case, the optimal decision was described with each stage of the problem, and in a small problem this will be sufficient. Generally, the record of optimal decisions and costs can be kept together as two tables. Each will have a column for every stage and a row for every discrete value of space that could be achieved. The entry in one will be the value of f , the other the optimal decision [The optimal decision could also be recovered from the table of optimal values following the logic that the recurrence $f_n(w) = \max(0 + f_{n+1}(w), V_n + f_{n+1}(w - W_n))$ means that $f_n(w)$ is either the same as $f_{n+1}(w)$ corresponding to not packing item n , or equal to $V_n + f_{n+1}(w - W_n)$ which means that item n is packed.].

This example was simple and straightforward, and readers will have worked out the best way of packing this small knapsack without needing so many calculations. However, when there are tens or hundreds of items, and a significant number of them need to be packed, the dynamic programming approach is worthwhile.

The simple model can be extended in several ways. It may be possible to pack multiple copies of an item in the knapsack. The value may be proportional to the number of copies packed, or there may be some other relationship between the value of a set of items and the number of items in the set. Economists have used the knapsack model when the value follows the law of diminishing returns; packing one spare set of clothes will have a value, but packing a second spare set will have a reduced value. (This phenomenon has been noted in treating the placing of advertising budgets as knapsack problems. Doubling the expenditure on advertising in a particular medium does not double the expected impact.) Another extension is when there are other constraints on the knapsack besides the

weight; the container to be packed into has two (or more) dimensions, such as weight and volume, and each item takes up some of each. Then the functions f will have one parameter for each dimension, each representing the amount of that resource dimension still available.

PRODUCTION MODELS

In many industrial processes, a machine can be used to produce a variety of products. By varying the fillings, different types of chocolate bars can be made on the same production line. By changing the quantity of the ingredients, different sizes of bars can be made on the same line. This is obviously of benefit to the producer, as it means that an expensive machine can be used efficiently. However, the saving in capital and maintenance costs compared with having several production machines is balanced by the expense and time of changing the nature of the item being made. So long production runs are desirable, but these mean that items have to be stored until they are needed.

One of the earliest production processes to be studied using a DP model was that for scheduling production for several future time periods, when the demand for the item was known exactly. Here, the time period is a month, but this is arbitrary. At the start of each month, a decision has to be made about whether to make any items in that month—and if so, how many—or not. Zero production implies that there are enough items in stock to supply all the orders for the month. Zero production has no production cost that is linked to the problem, while producing any number of items incurs the cost of starting a production run and the cost of making those items.

The time periods provide an obvious way of defining the stages. One can imagine a manager inspecting the inventory at the start of each month, counting how many items there are, and deciding whether or not to produce any more. For simplicity, one assumes that the items that are needed in 1 month can be produced in that month. If there are items in stock, then they will be used to meet that

month's demands, and any surplus will be held until the following month, and be subject to a charge for storage. So, in this model, the state is identified with the number of items found at the start of the month (or stage), and the decision is the number to produce, including the option to produce nothing. The single-stage cost will be the storage cost for the items that need to be held to the following month, plus the cost of production if it is appropriate. Letting h_n be the cost of storage per item from month n to month $n + 1$, demand in month n be D_n , and $A_n + C_n x$ be the production cost for x items when x is not 0, one has:

$$f_n(s) = \min(h_n(s - D_n) + f_{n+1}(s - D_n), \\ A_n + C_n x + h_n(s - D_n + x) \\ + f_{n+1}(s - D_n + x))$$

as the cost of the optimal policy from the start of month n , with s items in store. In the expression, the minimum is taken over all values of x such that $(s - D_n + x)$ is not less than 0 and x should not be larger than the amount that has still to be produced.

(Alternatively, one can combine the two alternatives into one expression, by defining a cost function $TC(n, x, s)$, which is equal to the cost of producing x items in month n plus the cost of holding $(s - D_n + x)$ to the next month. Then the recurrence becomes

$$f_n(s) = \min(TC(n, x, s) + f_{n+1}(s - D_n + x)),$$

taken over the same values of x as before.)

At the end of the planning period, at the end of N months, any value $f_{N+1}(s)$ is 0.

There may appear to be a great many calculations, but the problem is surprisingly simple. If there are no items in stock, then the decision is limited to a small number of alternative values. The production quantity should be enough for the current month, or the current month and the whole of one or more subsequent months. If there are items in stock, the rule just stated ensures that there will be enough for the current month. This result can be proved formally, but it is enough to follow this informal argument. Suppose it were ever optimal to produce items

in a month, which began with items in stock at the start. Now suppose that there had been one item less at the start of month i ; the cost of producing an extra item will be C_i . If this is less than the total cost associated with having one less item that was made in an earlier month and held in stock, then it is better to have fewer items in stock. The argument can be continued until there were no items in stock at the start of month i . If C_i is bigger than the total cost, then the number in stock should be increased to be at least as large as the demand for month i , which will not only reduce the cost per item, but also remove the fixed cost A_i of starting a production run in month i .

LINE BREAKING IN TeX

TeX and LaTeX are widely used computerized document preparation systems, which process text materials into an appropriate format for printing. The systems are used by many scientists because the systems were designed to produce attractive layouts for mathematical content. An important part of such a system is the ability to break a paragraph into lines. Many people use a word processor with the requirement that the text is justified (the left- and right-hand sides of the page appear as a straight line). When this happens, the space between words is increased on some lines, and if the appropriate option has been selected, some words may be hyphenated. Sometimes, if the lines are short, or the words are long, there will be many large spaces on the page, resulting in an ugly page.

In the development of TeX (LaTeX is similar) the creators decided to use a more sophisticated method of "Hyphenation and Justification" than the usual word processor algorithm, which lays out one line at a time, without referring to any other part of the paragraph. Their work is reported in [6] (and also in Chapter 14 of the TeXbook [7]) and it is based on a deterministic DP model. The input to the model is an entire paragraph; within this, all the possible places (break points) where a line of text could be broken are then identified. These will be spaces

between words and permitted hyphenation points within words. A paragraph begins and the model examines each possible decision for the break point at the end of the first line. The decision leads to a new state, described by the place where the next line will start and whether or not there is a hyphen. The process is repeated for each successive line, and the lines determine the stages of the DP formulation. The decision also generates a cost, which is a measure of how ugly the line will look by itself together with the previous line. The paper [6] discusses how to measure ugliness in terms of extra space between words, reduction of space between words, the need to hyphenate words, and whether or not the previous line ended with a hyphen. The ugliness of a paragraph is then found by combining the uglinesses of the lines in it.

Unlike most word processors, the algorithm in TeX does not break any lines in a paragraph until the whole paragraph is complete, and then determines the optimal (minimizing ugliness or maximizing attractiveness) layout for the whole paragraph.

This DP model is a shortest path problem in a slight disguise. The value given to a paragraph's appearance is found by combining the values for each line, and each line is determined by the states (break points) at either end. As an example, the paragraph below shows the break points as hyphens in a short paragraph, which was to fit into a small column, so that the first break appeared in the first "construction." The optimal layout for this paragraph is shown below.

In the United States, vast amounts of construction waste are produced every year. Construction waste accounts for a significant portion of the municipal waste stream of the United States.

In the United States, vast amounts of construction waste are produced every year. Construction waste accounts for a significant portion of the municipal waste stream of the United States.

JOB SCHEDULING

Many people and organizations have problems of scheduling work. DP is useful for solving some types of problems, which involve

schedules. The idea behind the use of DP in scheduling is that the optimal schedule for a set of jobs is made up of the optimal schedule for a subset of jobs followed by the optimal schedule for the complement of that subset given the later starting time(s) that results from having done some of the jobs. And thus one has the seeds of a DP formulation, because the problem has been broken into smaller parts in sequence. Consider a simple example of finding the best schedule for five jobs on one machine with the objective of minimizing the mean tardiness (or the total tardiness). Tardiness is measured as 0 if the job is completed early and if the job is late, it is the number of time units (using minutes here) late that the job is finished after its deadline.

Suppose that the jobs have deadlines as shown in the table below, and that the jobs take the different processing times listed.

Job	1	2	3	4	5
Processing time (min) $[p_j]$	24	8	24	31	18
Deadline (min from now) $[d_j]$	53	29	39	50	69

To consider this problem using DP, one needs to define the essential features of any such formulation. Therefore define the states of the system, a series of stages, an objective function, and a recurrence relation that connects the successive states and stages. The stages are comparatively obvious. The person responsible for devising the schedule has to decide which jobs to schedule next, and the decisions are effectively taken as each job finishes. Therefore, there are five stages corresponding to the need to schedule one, two, three, four, and five jobs respectively. At each stage there will be a number of possible states, corresponding to the possible sets of jobs that have been completed by that stage. The decision that answers the question "What next?", follows from considering the list of jobs that are waiting to be scheduled. The objective of the model is to minimize the mean tardiness, and as this is simply a multiple of the total tardiness, it is a straightforward transformation to the

problem to make minimizing the total as the objective.

When the scheduler decides on a job to be scheduled next, this decision fixes the tardiness for that job because the set of jobs which have already been finished has determined the time when the decision is being taken, the duration of the job being scheduled determines when it will finish, and the due date for the job will determine the contribution of that job to the total tardiness function. And thus it is possible to write down a recurrence relationship.

Suppose that the set of jobs to be scheduled is a set S , and that the decision is considered once all the jobs in a subset J of S have been completed. The time now will be $T(J) = \sum_j p_j$. The stage n will be the number of jobs already scheduled, that is, the total number of jobs that are in J . Take a job i as the next job to be completed. It will finish at time $T(J) + p_i$. If this is less than d_i , there is no tardiness. If not, and if job i is completed too late, it will have a tardiness $T(J) + p_i - d_i$. Mathematically, the tardiness

is written as $\max(0, T(J) + p_i - d_i)$. Then the total tardiness which follows from scheduling one of the jobs not in J , job i say, will be

$$\max(0, T(J) + p_i - d_i) + f_{n+1}(J + \{i\}).$$

All that is needed to find $f(J, T)$ is to look at all possible values of i , calculate the tardiness contribution, and select the job i , which gives the smallest value. So, one has

$$f_n(J) = \min[\max(0, T + p_i - d_i) + f_{n+1}(J + \{i\}, T + p_i)]$$

taken over all i that are not in J .

Here the tardiness gives the single-stage “cost” and this is followed by the optimal policy for the set of jobs that will have been scheduled at the time when the next decision is made. It is useful to record the time ($T(J)$) as well as the set (J) for ease of calculation. To illustrate this formulation, suppose stage 1 has been calculated to be as shown in table below.

The Set of Jobs, J	{2,3,4,5}	{1,3,4,5}	{1,2,4,5}	{1,2,3,5}	{1,2,3,4}
Job not in J	1	2	3	4	5
$T(J)$	81	97	81	74	87
$F_1(J)$	52	76	66	55	36

Then the calculation for f_2 will be based on the possible sets J with three finished jobs; one such will be $J = \{1, 3, 4\}$ and this will have $T = 79 (= 24 + 24 + 31)$. If job 2 is done next, it will finish at time 87, and be 58 min tardy, and the table above shows that the contribution from scheduling job 5 last will be 36 min. So, scheduling job 2 next contributes $58 + 36 = 94$ min. Alternatively, scheduling job 5 next contributes $28 + 76 = 104$ min. There are 10 possible sets of 3 jobs at stage 2 to consider; 10 at stage 3; 5 at stage 4; and 1 (no jobs scheduled) at stage 5. The best schedule is 2-3-1-5-4.

This scheduling problem is one for which the curse of dimensionality applies. The number of states that have to be examined

is 2 raised to the power of the number of jobs in the set S . So with 5 jobs in S , there are 32 states to be considered. With twice that number, there would be 1024 states. Even so, these numbers are considerably less than the number of schedules possible, which would be 120 (for 5 jobs) and 3,628,800 (for 10 jobs).

INTRODUCTION

Global optimization is a very active and exciting branch of the optimization tree. It mainly deals with problems that involve nonconvexity either in the objective function or in the constraints. The nonconvexity of the functions makes the problem intrinsically hard due to the presence of multiple local optima and it is also the reason for it to be NP-hard. Global optimization is a very general optimization area that involves both continuous and discrete variables. As will be seen in the article, most discrete optimization problems can be transformed to a continuous problem by adding some nonconvex constraints, for example, the complementarity constraints. Global optimization includes a variety of problems that arise in many applications such as economics, biology, medicine, management, sciences, engineering, etc. Also numerous algorithms were proposed and studied extensively to solve these problems. This is an area with abundant scope for research for new problems,

applications, and algorithms. In this survey, we focus on deterministic computational methods in global optimization.

This article adopts a problem-based organization, where we focus on a specific type of problem in each section and several available deterministic computational methods are discussed for each problem. In the section titled “Lipschitz Optimization,” we show the Lipschitz optimization problem and solution methods. In the section titled “DC Optimization,” we discuss DC optimization, its optimality conditions, and a few solution algorithms. The section titled “Monotone Optimization” discusses monotone optimization. In the section titled “Quadratic Programming,” we discuss quadratic programming and optimality conditions. Also several algorithms for both equality-constrained and inequality-constrained quadratic programs are discussed. In the section titled “General Concave Minimization,” we discuss general concave optimization. In the section titled “Linear Complementarity Problem, and Mathematical Programs with Complementarity Constraints,” we focus on linear complementarity problems and briefly mention mathematical programs with complementarity constraints. In the section titled “Discrete Optimization Problems,” we discuss the relationship between discrete optimization and continuous optimization. A few transformations from discrete to continuous optimization are also shown. And, the final section concludes the article.

LIPSCHITZ OPTIMIZATION

In Lipschitz optimization problem (LOP), we deal with real valued objective and constraint functions that are Lipschitz continuous over a compact set with known Lipschitz constants. Consider the following LOP:

$$\text{Minimize } f_0(x) \quad (1)$$

$$\text{s.t. } x \in P, \quad (2)$$

$$f_i(x) \leq 0, \quad i = 1, \dots, m, \quad (3)$$

where $f_i(x)$, $i = 0, \dots, m$ are Lipschitz continuous on P , such that they satisfy

$$|f_i(x_1) - f_i(x_2)| \leq L_i \|x_1 - x_2\|,$$

for all $x_1, x_2 \in P$, with the Lipschitz constant $L_i = L_j(f_i, P)$, $i = 0, \dots, m$. Let us define the set C as

$$C = \{x \in P : f_i(x) \leq 0, \quad i = 1, \dots, m\},$$

which we assume is compact.

Algorithm:

(Initialization)

Step 1 : $m_X \leftarrow \frac{(a+b)}{2}$, $Q \leftarrow \{a, b, m_X\}$, $\alpha = \min\{f(x) : x \in Q\}$ (α is an upper bound on the optimal solution)

Step 2 : Find $x^1 \in Q$, such that $\alpha = f(x^1)$

Step 3 : Set $\mu(X) \leftarrow \max\{\max\{f(a), f(b)\} - L\|b - a\|, f(m(X)) - L\frac{\|b-a\|}{2}\}$ (lower bound on the optimal value)

Step 4 : Set $k \leftarrow 1$, $\mathcal{M} \leftarrow X$, $\mu \leftarrow \mu(X)$

(Iteration k)

Step 5 : If $\mu = \alpha$ return x^k as the optimal solution

Step 6 : Find $b_j - a_j = \max\{b_i - a_i, \quad i = 1 \dots n\}$

Step 7 : Set $a^1 \leftarrow a$, $b^1 \leftarrow \left\{b_1, \dots, \frac{(b_j+a_j)}{2}, \dots, b_n\right\}^T$

Step 8 : Set $a^2 \leftarrow \left\{a_1, \dots, \frac{(b_j+a_j)}{2}, \dots, a_n\right\}^T$, $b^2 \leftarrow b$

Step 9 : Set $R_1 = \{x : a^1 \leq x \leq b^1\}$, $R_2 = \{x : a^2 \leq x \leq b^2\}$

Step 10: Set $m(R_1) = \frac{(a^1+b^1)}{2}$, $m(R_2) = \frac{(a^2+b^2)}{2}$

Step 11: Set $\mu(R_1) = \max\left\{\mu(X), \max\{f(a^1), f(b^1)\} - L\|b^1 - a^1\|, f(m(R_1)) - L\frac{\|b^1-a^1\|}{2}\right\}$

Step 12: Set $\mu(R_2) = \max\left\{\mu(X), \max\{f(a^2), f(b^2)\} - L\|b^2 - a^2\|, f(m(R_2)) - L\frac{\|b^2-a^2\|}{2}\right\}$

Step 13: Set $Q \leftarrow \{x^k, b^1, m(R_1), a^2, m(R_2)\}$, $\alpha \leftarrow \min\{f(x) : x \in Q\}$

Step 14: Set $k \leftarrow k + 1$, $\mathcal{M} \leftarrow \mathcal{M} \setminus X \cup \{R_1, R_2\}$, $D \leftarrow \{X \in \mathcal{M} : \mu(X) \leq \alpha\}$

Step 15: Set $\mu = \begin{cases} \min\{\mu(X) : X \in D\} & \text{if } D \neq \emptyset \\ \alpha & \text{if } D = \emptyset \end{cases}$

Step 16: Choose $X \in D$ with $\mu(X) = \mu$ and update a, b such that $X = \{x : a \leq x \leq b\}$

Step 17: Find $x^k \in Q$, such that $\alpha = f(x^k)$

Step 18: Goto step 5

Partition Strategies

We first discuss a branch and bound method for an LOP, where the feasible set is a rectangle $\{x \in \mathcal{R}^n : a \leq x \leq b, a < b \in \mathcal{R}^n\}$. Consider the following LOP with rectangular feasible region.

$$\text{Maximize } f(x) \quad (4)$$

$$\text{s.t. } x \in X = \{x \in \mathcal{R}^n : a \leq x \leq b, \quad a < b \in \mathcal{R}^n\}, \quad (5)$$

where $a = \{a_1, a_2, \dots, a_n\}^T$, $b = \{b_1, b_2, \dots, b_n\}^T \in \mathcal{R}^n$, $a < b$, and $f : X \rightarrow \mathcal{R}$ with the Lipschitz constant $L = L(f, X)$. The algorithm bisects the rectangles at the midpoint of the longest edge.

The convergence of the algorithm is a consequence of the following lemma [1].

Lemma 1. *Successive bisections of n -rectangles at the midpoint of the one of its longest edges is exhaustive.*

We discuss a partition method in which the feasible region is an n -dimensional polytope X to get the following global optimization problem:

$$\text{Minimize } f(x) \quad (6)$$

$$\text{s.t. } x \in X, \quad (7)$$

where $f : X \rightarrow \mathcal{R}$ is a Lipschitz function with the Lipschitz constant $L = L(f, X)$ and X is an n -dimensional polytope. Let $S_0 \supset X$ be an n -simplex that tightly approximates X . We employ the following partitioning strategy to solve the above problem.

We partition S_0 into n -simplices S with known vertex set $V(S)$, such that $S_0 = \bigcup_{i=0}^n S_i$, $S_i \cap S_j = \emptyset$, for $i \neq j$. For each simplex S , we determine a lower bound

$$\mu(S) \leq \min \{f(x) : x \in S \cup D\}.$$

We determine a nonempty set $Q \subset D$ and determine the upper bound on the optimal value $\alpha = \min\{f(x) : x \in Q\}$. After deleting the simplices S with $\mu(S) \geq \alpha$ or $S \cap D = \emptyset$, we proceed to the next iteration. For details of the implementation of the lower bound and upper bound computation, we refer the reader to Horst *et al.* [1] and Pintér [2]. There are several techniques to estimate the lower bound.

There are several other partition algorithms that are available in the literature. We refer the reader to Hansen and Walster [3], Neumaier [4], Ratschek and Rokne [5], and Kearfott [6] for a detailed list of all of these and details about their implementation.

Covering Method

Numerous algorithms have been proposed to solve the Lipschitz optimization problem $\max\{f(x) : x \in X, a \leq x \leq b\}$ to an ϵ optimal value. We try to find $x_{\text{opt}} \in X$, $f_0(x_{\text{opt}}) \leq f_0^* + \epsilon$, where f_0^* is the global optimal value and

$f_0(x_{\text{opt}})$ is the ϵ -optimal value and x_{opt} is the corresponding point. An algorithm is ϵ -convergent if it solves this above problem in finite number of iterations.

The following theorem is established from the Lipschitz property of the objective function f .

Theorem 1 [7]. *There is no algorithm with finite convergence for the optimization problem, where we maximize a Lipschitz function with known Lipschitz constant over a hyper-rectangular region, such that it attains the global optimal solution x^* and prove the optimality in finite number of iterations unless f satisfies the following:*

$$\begin{aligned} \exists \delta > 0 \text{ such that } f(x) &= f(x^*) - L|x - x^*|, \\ \forall x &\in [x - \delta, x + \delta] \cap [a, b]. \end{aligned} \quad (8)$$

The implication of the above theorem is that around the neighborhood of x^* there is a sawtooth with slopes $-L$ and L to its left and right, respectively.

Piyavskii's algorithm maximizes a univariate Lipschitz's function over a hyper rectangular feasible region. The function f is upper bounded by a piecewise linear function F . If we could find the function F and a point x_{opt} such that $f(x_{\text{opt}})$ is close to the optimal value of f^* and the function F with maximum value as low as possible, we could provide an ϵ -optimal solution to our Lipschitz optimization problem. This method is called *covering method*, since it constructs a sequence of upper envelope functions $F_k(x)$, where k denotes the k th iteration, that satisfy

$$\begin{aligned} F_k(x) &\geq f(x), \quad \forall x \in [a, b], \quad k = 1, 2, \dots, \\ F_k(x) &\geq F_{k+1}(x), \quad \forall x \in [a, b], \quad k = 1, 2, \dots, \\ F_k(x_j) &= f(x_j), \quad j = 1, 2, \dots, n, \end{aligned}$$

where $\{x_j : j = 1, 2, \dots, n\}$ is a sequence of feasible solutions and the upper envelope function $F_k(x)$ is defined in the following theorem.

Theorem 2 [8,9]. *The one-step optimal upper bounding function F_k for f on the interval $[a, b]$ is*

$$F_k(x) = \min_{i=1,2,\dots,k} g_i^P(x), \quad (9)$$

where $g_i^P(x) = f(x_i) + L|x - x_i|$.

This is because of the property of Lipschitz function, $|f(x) - f(x_i)| \leq L|x - x_i|$, $\forall x \in [a, b]$, and then $g_i^P(x)$ is greater or equal to $f(x)$ for all i and $x \in [a, b]$. Hence, the minimum of all $g_i^P(x)$'s is greater than $f(x)$, which means an upper envelope of $f(x)$.

The shape of this upper bounding function is a sawtooth. One consequence of the

above theorem is that within a subinterval $[c, d] \subset [a, b]$, the best upper bound of the function f depends only on the values of f at the evaluation points within the subinterval $[c, d]$, but the best bound of $[c, d]$ could be dependent on points outside $[c, d]$. The peak point of the sawtooth cover F_k between two consecutive evaluation points x_i and x_{i+1} in the interval $[a, b]$ is given by $\frac{x_i + x_{i+1}}{2} + \frac{f(x_{i+1}) - f(x_i)}{2L}$.

Algorithm (Piyavskii)

Initialization

Step 1 : $k \leftarrow 1, x_k \leftarrow \frac{a+b}{2}$

Step 2 : $x_{\text{opt}} \leftarrow x_k$

Step 3 : $F_k(x_{\text{opt}}) \leftarrow f(x_{\text{opt}}) + L \frac{(b-a)}{2}$

Step 4 : $F_k(x) \leftarrow f(x_k) + L|x - x_k|$

Iteration

Step 5 : **If** $F_k(x_{\text{opt}}) - f(x_{\text{opt}}) \leq \epsilon$ **Then** return x_k as optimal solution

Step 6 : $x_{k+1} \leftarrow \arg \max_{x \in [a, b]} F_k(x)$

Step 7 : **If** $f(x_{k+1}) > f(x_{\text{opt}})$ **Then** $x_{\text{opt}} \leftarrow x_{k+1}$

Step 8 : $F_{k+1}(x) \leftarrow \min_{i=1,2,\dots,k+1} F_{k+1}(x)$

Step 9 : $F(x_{\text{opt}}) \leftarrow \max_{x \in [a, b]} F_{k+1}(x)$

Step 10: Goto Step 5

The peak point of a sawtooth is an upper bound of the function f and at each iteration the largest upper bound or highest peak is identified and chosen as the evaluation point. In other words, the sawtooth with the highest peak point is broken down at each iteration. This similarity between branch and bound method and Piyavskii's algorithm was observed by Horst and Tuy [8]. The proof of convergence of Piyavskii's algorithm could be found in Piyavskii [9], Hansen and Jaumard [10], and Pintér [2]. Also this algorithm can be easily generalized to higher dimension problems, but the problems become much harder to solve.

DC OPTIMIZATION

The objective functions, or the constraint set, that are not convex of many optimization problems could be written as the difference of two convex functions (DC functions). In

this way, we try to overcome the inherent difficulty in the optimization problems due to the nonconvexity and develop efficient methods to solve them.

A function $f : X \rightarrow \mathcal{R}$, where X is convex, is a DC function on X , if $\forall x \in X$ we have

$$f(x) = g(x) - h(x),$$

where g, h are convex functions on X .

An optimization problem is a DC optimization problem if it could be written in the following form:

$$\text{Minimize } f_0(x) \quad (10)$$

$$\text{s.t. } x \in X \subset \mathcal{R}^n, \quad (11)$$

$$f_i(x) \leq 0, \quad i = 1, \dots, m. \quad (12)$$

Also, $f_i(x)$, ($i = 0 \dots m$) are DC functions and X is a compact convex set. Any DC problem could be reduced to a canonical DC (CDC) problem, where a linear function is

minimized over the intersection of a compact convex set, X , and an open convex set. The open convex set could be represented by the reverse convex constraint,

$$h(x) \geq 0,$$

where $h : \mathcal{R}^n \rightarrow \mathcal{R}$ is a convex function.

Optimality Conditions

We provide the optimality conditions for the DC optimization problems without the proofs, as the emphasis of the article is on computational methods and the proofs are available in Horst *et al.* [1] and Tuy [11]. Let us consider the DC optimization problem

$$\omega^* = \min g(x) - h(x) : x \in X, \quad (13)$$

where g and h are convex functions and X is a compact convex set.

Theorem 3. $x^* \in X$ is an optimal solution to Equation (13) if and only if there is a t^* such that

$$0 = \inf \{ -h(x) + t : x \in X, \\ g(x) - t \leq g(x^*) - t^* \}.$$

The geometric optimality conditions could be stated as follows.

Theorem 4. $x^* \in X$ is an optimal solution to Equation (13) if and only if

$$\text{epi } \bar{g} | X \subset \text{epi } h | X,$$

where $\bar{g}(x) = g(x) - (g(x^*) - h(x^*))$.

For any function f , we define $\text{epi } f | X = \{(x, t) \in \mathcal{R}^n \times \mathcal{R} : x \in X, f(x) \leq t\}$. Another way of stating the above theorem is as follows.

Theorem 5. $x^* \in X$ is an optimal solution to Equation (13) if and only if

$$\partial X_\epsilon h(x^*) \subset \partial X_\epsilon g(x^*), \quad \forall \epsilon \geq 0.$$

For any function f , we define $\partial X_\epsilon f(\bar{x}) = \{s : f(\bar{x}) - f(x) + s^T(x - \bar{x}) - \epsilon \leq 0, \forall x \in X\}$.

Branch and Bound

We discuss the branch and bound method for the following DC optimization problem in this section.

$$\text{Minimize } f_0(x) \quad (14)$$

$$\text{s.t. } f_i(x) \leq 0, i = 1, \dots, m, \quad (15)$$

$$x \in X \subset \mathcal{R}^n, \quad (16)$$

where $f_i(x) = g_i(x) - h_i(x)$, $i = 0, \dots, m$, are DC functions and X is a polytope. Let F be the feasible set of the above global optimization problem.

Initialize. Construct a simplex $S^1 \supseteq X$ and compute $l(S^1)$, the lower bound for f_0 over the set $S^1 \cap F$. Determine a set $M^1 \subset S^1 \cap F$. Compute the upper bound $g^1 = \{\text{Minimize } f_0(x) : x \in M^1\}$. Choose a point x^1 such that $f(x^1) = g^1$. Set, $l^1 = l(S^1)$, $R^1 = \{S^1\}$ and $k = 1$.

Iteration k . If $l^k = g^k$, then return $x^* = x^k$ as the optimal solution, else break down S^k into r disjoint simplices S_i^k , $i = 1 \dots r$, such that $S^k = \cup_{i=1}^r S_i^k$. For each $i = 1 \dots r$, compute lower bounds $l(S_i^k) \geq l^k$ for f_0 on $S_i^k \cap F$. Let $M_i^k \subset S_i^k$ and set $M^{k+1} = M^k \cup \{M_i^k, i = 1 \dots r\}$. Compute $g^{k+1} = \text{Minimize } f_0(x) : x \in M^{k+1}$, and choose $x^{k+1} \in M^{k+1}$, such that $f(x^{k+1}) = g^{k+1}$. Set $R^{k+1} = \{R^k \setminus S^k \cup S_i^k, i = 1 \dots r\}$. Delete all $S \in R^{k+1}$, where $l(S) \geq g^{k+1}$ and R^{k+1} be the remaining set. If $R^{k+1} = \emptyset$ then set $l^{k+1} = g^{k+1}$, else set $l^{k+1} = \{\min l(S) : \forall S \in R^{k+1}\}$, $S^{k+1} = \{\text{argmin } l(S) : \forall S \in R^{k+1}\}$, $k = k + 1$ and go to iteration k .

We refer the reader to Tuy [11] for the details of the implementation of simplex breakdown, computation of lower bound and upper bound in the above algorithm.

Outer Approximations

We present the sketch of an outer approximation method for solving the CDC optimization problem. The complete algorithm could be referred in Tuy [11,12] and Tuy and Horst

[13]. Consider the following CDC problem:

$$\text{Minimize } f(x) \quad (17)$$

$$\text{s.t. } x \in X \quad (18)$$

$$h(x) \geq 0, \quad (19)$$

where f is a linear function, X is a compact convex set, and h is a convex function. Let us define the set C as

$$C = \{x : h(x) \leq 0\}.$$

Let $\text{int } C$ refer to the interior of the set C . The regularity condition for the above CDC problem is stated as

$$\inf\{f(x) : x \in X \setminus \text{int } C\} = \inf\{f(x) : x \in X \setminus C\}. \quad (20)$$

Set $D(\gamma) = \{x \in X : f(x) \leq \gamma\}$. Under the above regularity assumption, solving the CDC problem is equivalent to finding:

$$\gamma^* = \inf \{\gamma : D(\gamma) \setminus C \neq \emptyset\}.$$

We begin the algorithm with a known feasible solution $\bar{x}$ and set $\gamma = f(\bar{x})$. As in many outer approximation, we determine a polytope P^1 that outer approximates the set $D(\gamma)$. Let V be the vertex set of the polytope P^1 . Now, we seek a point $z^1 \in P^1 \setminus C$ or prove that $P^1 \subset C$. This could be accomplished by checking whether $\{\max h(x) : x \in V\} \leq 0$. If $P^1 \subset C$, then we terminate the iteration. Otherwise, we improve z^1 to $x^1 \in \partial X \cap \partial C$, the intersection of the boundaries of X and C . If $x^1 \notin X$ and hence infeasible, we can separate z^1 from the set $X \supset D(\gamma)$ with a hyperplane $l(x) \leq 0$ and set $P^2 = P^1 \cap \{x : l(x) \leq 0\}$ and restart the iteration. If $x^1 \in X$, and we have $f(x^1) = \gamma^1 \leq \gamma$, then we have $f(x) \leq \gamma^1$ strictly separating z^1 from $D(\gamma^1)$. We set $P^2 = P^1 \cap \{x : f(x) \leq \gamma^1\}$ and restart the iteration. We either terminate at a polytope $P^k \subset C$, where the current γ satisfies $D(\gamma) \subset C$, as $P^k \supset D(\gamma)$ or we generate a sequence of polytopes $P^1 \supset P^2 \dots$, such that $P^k \supset D(\gamma^k)$ and $z^k \in P^k \setminus C$. The terminating γ value is the optimal value of the CDC.

Polyhedral Annexation Method (PA)

Polyhedral annexation method (PA) method is also referred to as the *dual method* or *inner approximation method*. Let E^* be the polar of a set E defined by

$$E^* = \{y \in \mathcal{R}^n : y^t x \leq 1, x \in E\}.$$

Now the dual feasibility problem is based on the fact that

$$D(\gamma) \subset C \Leftrightarrow C^* \subset D(\gamma)^*.$$

The dual methods can overcome the dimensionality problems that might arise in the primal methods. In the PA method, we generate a sequence of polyhedrons such that, $P_1 \subset P_2 \dots \subset C$. If a polyhedron $P_k \supset D(\gamma)$, then the current value of γ is the optimal value. If we find a point $x \in D(\gamma) \subset C$, we can find a better feasible solution and continue the procedure after updating the incumbent solution. The procedure is similar to the outer approximation method that we discussed, but for the dual. If S_k is the polar of P_k , then $S_k \supset C^*$. This could be inferred from the definition of the polar. So we generate a sequence $S_1 \supset S_2 \dots C^*$ and we stop when we find a $S_k \subset D(\gamma)^*$ or if a point $y \in C^* \setminus D(\gamma)^*$ is found. More details about the implementation of the algorithm could be found in Tuy [11,14].

Covering Method

Similar to Piyavskii's algorithm [9], while solving a maximization problem, $\max_{x \in X} f(x)$, some authors [15–18] proposed covering methods for a function with bounded second-order derivative, that is,

$$f(x) \leq f(y) + [\nabla f(y)]^T(x - y) + K\|x - y\|^2, \\ x, y \in X,$$

where X is the feasible region. By this assumption, the upper envelope function can be constructed as follows:

$$F_k(x) = \min_{i=1, \dots, k} g_i^B(x),$$

where $g_i^B(x) = f(x_i) + [\nabla f(x_i)]^T(x - x_i) + K\|x - x_i\|^2$. Baritomp and Cutler [16] generalized this to the following:

$$g_i^B(x) = f(x_i) + [\nabla f(x_i)]^T(x - x_i) + (x - x_i)^T H(x - x_i),$$

with a positive definite H . Sometimes, solving the maximization problem of the upper envelope function, $F_k(x)$, over the feasible region is as hard as solving the original problem. Blanquero and Carrizosa [19] proposed a new upper envelope function for the DC functions and showed that the above approach by Baritomba and Cutler [16] is just a special case of applying DC decomposition on $f(x)$. Suppose function $f(x)$ is a DC function, and then it can be decomposed as follows:

$$f(x) = f_1(x) + f_2(x), \quad \forall x \in X,$$

where $f_1(x)$ is a convex function and $f_2(x)$ is a concave function. By taking a first-order approximation of $f_2(x)$ at y , we can have

$$f(x) \leq f_1(x) + f_2(y) + \xi_2^T(y)(x - y),$$

where $\xi_2(y)$ is a subgradient of $f_2(x)$ at y . Then we can define that

$$g_i(x) = f_1(x) + f_2(x_i) + \xi_2^T(x_i)(x - x_i),$$

and obtain a new upper envelope function. It is interesting to note that if we decompose a function as

$$f(x) = x^T H x + [f(x) - x^T H x],$$

which is a DC decomposition, we will get the same upper envelope function as discussed by Baritomba and Cutler [16].

MONOTONE OPTIMIZATION

Nonconvex programs with special structures such as monotone functions and d.m. (difference of monotone) functions have been

given a lot of attentions in the recent past. Monotonic optimization arises in many engineering and economics fields and many nonconvex problems such as multiplicative programming, indefinite quadratic programming, and Lipschitz optimization [20]. For the interested readers, a number of recent surveys and works [20–23] are available on monotone optimization.

A monotone optimization problem could be stated as

$$\min f(x) : x \in G \cap H,$$

where f is monotone nondecreasing function, which is monotonely nondecreasing on every ray in the orthant (i.e., $f(y) \geq f(x)$ whenever $x \leq y$), and $G = \{x \in \mathbb{R}^n : g_i(x) \leq 0, i = 1 \dots l, x \in [a, b]\}$ and $H = \{x \in \mathbb{R}^n : h_i(x) \geq 0, i = 1 \dots k, x \in [a, b]\}$, where g_i and h_i are monotone nondecreasing lower and upper semicontinuous functions, respectively. G is a compact *normal set* defined by the property $x \leq y \in G \Rightarrow x \in G$ and H is a closed *reverse normal set* defined by the property $x \geq y \in H \Rightarrow x \in H$. A detailed theory on normal sets and lower semicontinuous functions could be found in Tuy [20]. Now we proceed to describe a popular algorithm, polyblock outer approximation, for solving d.m. problems. The idea behind the algorithm is to approximate the normal sets with *polyblocks* in $[a, b] \in \mathbb{R}_+^n$, defined as the union of intersection of finite set of boxes $[a, z] \subset [a, b], z \in T$ and the set T is called the *vertex set* of the polyblock. We define a vertex v^k as *proper* if it is not dominated by any other vertex in T , that is, $v^k \notin [a, v'], \forall v' \in T$. All other elements of T are *improper*. We refer the reader to Tuy [20] and Rubinov *et al.* [21] for more details about polyblocks and their properties. The idea behind the algorithm is to construct a series of polyblocks approximating $G \cap H \subset P_k \subset \dots \subset P_2 \subset P_1$.

Algorithm (Polyblock outer approximation)

Initialization

Step 1: Select a tolerance $\epsilon \geq 0$, set $k = 0$

Step 2: Take $P_k = [a, b], T_k = b$

Step 3: Let the current best feasible solution be $\bar{x}^k$ and the corresponding objective value (CBV) = $f(\bar{x}^k)$ (if no feasible solution is found, then CBV = ∞)

Iteration

Step 4: Let L_k^1 be the set of all vertices $v \in T_k \notin H$ and L_k^2 be the set of all vertices with $f(v) \leq CBV + \epsilon$, let $\tilde{T}^k = T_k \setminus L_k^1 \cup L_k^2$

Step 5: If $\tilde{T}^k = \emptyset$, then terminate with $\bar{x}^k$ as the current best feasible solution if $CBV > -\infty$, else problem is infeasible

Step 6: if $\tilde{T}^k \neq \emptyset$ compute $v^k = \arg \max\{f(v) : v \in \tilde{T}^k\}$ and compute $x^k = \pi_G(v^k) = \lambda v^k$, $\lambda = \max\{\alpha > 0 : \alpha v^k \in G\}$, if $x^k \in G$, then we are done and return the solution v^k is an optimal solution

Step 7: Let T_{k+1} be the set obtained from $\{\tilde{T}^k \setminus v^k\} \cup \{v^k - (v_i^k - x_i^k)e^i, i = 1 \dots n\}$ after removing the improper vertices, set $k = k + 1$ and goto step 4

Many enhancements of this algorithm and competing algorithms have been developed in the recent years [22,23].

QUADRATIC PROGRAMMING

Quadratic programming (QP) is a very important type of continuous optimization problem by itself. It arises in many applications, such as portfolio theory, linear regression, VLSI design, optimal control, and optimal power flow. Also, it acts as the subproblem of many important methods, such as sequential quadratic programming and augmented Lagrangian methods. QP problems are optimization problems with quadratic objective function and linear constraints as follows:

$$\begin{aligned} \text{Minimize} \quad & f(x) = \frac{1}{2}x^T Qx + c^T x \\ \text{s.t.} \quad & Ax \leq b, \end{aligned} \quad (21)$$

where Q is a real symmetric $n \times n$ matrix, and A is $m \times n$ matrix composed of row vectors $a_i, i = 1, \dots, m$, and c and b are $n \times 1$ and $m \times 1$ column vectors, respectively. The characteristics of the above problem (21) heavily depend on the structure of Q . If Q is positive semidefinite, the QP problem is convex and its KKT point is a global optimal solution. If Q is negative semidefinite, then $f(x)$ is concave and it is a quadratic concave programming problem. If Q has both positive and negative eigenvalues, it is called *indefinite QP*.

For the convex QP, there exist many solution methods among which some are polynomial algorithms. However, we focus here on nonconvex QP, which has either negative semidefinite or indefinite Q matrix. No polynomial algorithm is known for the nonconvex QP problems since these problems

are NP-hard. For concave QP, if a global optimum exists, then a global optimal solution exists among extreme points. For indefinite QP, the global optimal solution is not necessarily attained at an extreme point, but it is surely at the boundary of the polyhedron.

Optimality Conditions

Since most of the QP algorithms are dealing with the KKT conditions of the problem, we show here the KKT (first-order optimality) conditions as follows:

$$Ax \leq b, \quad (22)$$

$$Qx + c + A^T \lambda = 0 \quad \text{and} \quad \lambda \geq 0, \quad (23)$$

$$(Ax - b)^T \lambda = 0, \quad (24)$$

where λ is the dual vector (Lagrangian multipliers). Any point satisfying the above conditions, (22)–(24), is called a *KKT (first-order critical) point*. Inequality (22) is always referred to as the *primal feasibility*, and Equation (23) is the *dual feasibility* and Equation (24) is the *complementary slackness*. Since $\lambda \geq 0$ and $Ax \leq b$, Equation (24) is equivalent to $(a_i x - b_i) \cdot \lambda_i = 0, i = 1, \dots, m$. Moreover, a KKT point is called *strictly complementary* if and only if $(a_i x - b_i)$ and λ_i do not equal to 0 simultaneously.

Many algorithms try to find a weak first-order critical point, because finding the global optimal solution in polynomial time is very difficult. The active set at x is composed of all indices at which the linear constraints are binding, that is,

$$I(x) = \{i \mid a_i x = b_i\}.$$

A second-order critical point is a KKT point satisfying the following condition:

$$s^T Q s \geq 0, \quad \forall s \in \mathcal{S}(x), \quad (25)$$

where

$$\mathcal{S}(x) = \left\{ s \mid \begin{aligned} &a_i s = 0, \quad \forall i \in I(x) \cap \{i \mid \lambda_i > 0\}, \quad \text{and} \\ &a_i s \geq 0, \quad \forall i \in I(x) \cap \{i \mid \lambda_i = 0\} \end{aligned} \right\}.$$

If strict inequality holds in Equation (25) for $s \neq 0$, x is referred to as *strong second-order critical point*.

To define a weak second-order critical point, let

$$\mathcal{S}'(x) = \{s \mid a_i s = 0, \quad \forall i \in I(x)\}.$$

Then a weak second-order point is a KKT point such that $s^T Q s \geq 0, \quad \forall s \in \mathcal{S}'(x)$. Weak second-order critical points are easier to obtain than (strong) second-order critical ones. By the definitions above, a weak second-order critical point is also second-order critical if it is strictly complementary.

Different techniques are used to solve QP problems, according to different constraints' structures of QP, mainly equality-constrained and inequality-constrained QP.

Equality-Constrained QP

The equality-constrained QP is as follows:

$$\begin{aligned} \text{Minimize} \quad & f(x) = \frac{1}{2} x^T Q x + c^T x \\ \text{s.t.} \quad & Ax = b. \end{aligned} \quad (26)$$

To obtain a KKT point x^* , we need to solve the following linear equation:

$$\begin{bmatrix} Q & -A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} x^* \\ \lambda^* \end{bmatrix} = \begin{bmatrix} -c \\ b \end{bmatrix}. \quad (27)$$

By rearranging and substitution, $x^* = x + s$ (x is an estimate of x^* and s is the difference), we can rewrite Equation (27) as

$$\begin{bmatrix} Q & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} -s^* \\ \lambda^* \end{bmatrix} = \begin{bmatrix} d \\ g \end{bmatrix}, \quad (28)$$

where $s = x^* - x$, $d = c + Qx$, and $g = Ax - b$.

Instead of solving linear equations (27), we solve equations (28) where the matrix is

symmetric, making it easier to handle. The symmetric matrix in Equation (28) is referred to as *KKT matrix* usually denoted by K , which is always indefinite.

There are mainly two branches of methods to solve Equation (28), direct solution methods and iterative solution methods.

In direct solution methods, full KKT system factorization is the most basic one. We can perform the Gauss elimination method to solve it, which does not take advantage of symmetry. A better way is to exploit symmetric indefinite factorization, which is very effective in a number of problems. When Q is of full rank and can be easily inverted, we can also use the Schur-complement method. By rearranging the terms of Equation (28), we can get

$$\begin{aligned} A Q^{-1} A^T \lambda^* &= A Q^{-1} d - g, \\ s &= Q^{-1} A^T \lambda^* - d. \end{aligned}$$

Q , however, is not always nonsingular. In the singular cases, null space methods are usually used. Interested readers may refer to Nocedal and Wright [24].

For very large systems or with parallel computation, the iterative method is a better choice. Conjugate gradient (CG) method is the most basic and prominent method of this type. CG can be applied directly to the reduced system of QP (26). In the reduced system, x is decomposed to two parts as follows:

$$x = Yx_1 + Zx_2,$$

where Z is the $n \times (n - m)$ null space matrix of A , Y is a matrix such that $[Y|Z]$ is nonsingular. The problem is reduced to solving the following linear equations by CG method,

$$Z^T Q Z x_2 = -Z^T Q Y (A Y)^{-1} - Z^T c. \quad (29)$$

To improve the convergence rate, usually preconditioning is introduced to the CG method. The CG method works with the null space matrix Z at each step, which makes its performance greatly affected by the choice of Z . The projected CG method will not use Z explicitly, which can overcome the poor choice of Z . Also, preconditioning can be applied to the projected CG method to enhance convergence.

Inequality-Constrained QP

Inequality-constrained QPs are more general than the equality-constrained ones because of the linear inequality constraints. However, this makes the problem harder and we cannot just solve a linear system to get the optimal solution most of the time. The most basic but time-consuming method is enumerative method, which is listed here to give some basic ideas. Active-set method usually is a directed enumerative method, which is good for small and medium-size QPs. For large-scale QPs, generally interior point method is a better choice. However, if we solve a sequence of related problems, active-set method performs better because of its properties that are explained below.

Enumerative Method. For the nonconvex QPs, the optimal solutions occur on the boundary of the feasible region. At the optimal solution x , by the notion of active set $A(x)$, the KKT conditions reduce to the following linear equations:

$$\begin{aligned} Qx + A^T\lambda &= -c, \\ a_ix &= b_i, \quad i \in A(x), \\ \lambda_i &= 0, \quad i \in \{1, 2, \dots, m\} \setminus A(x). \end{aligned}$$

Of course, we can enumerate all the possible choice of active set $A(x)$ and solve the above linear system and check if they are in the feasible region. If we are not lucky, this at most requires $2^m(m+n)^3$ arithmetic operations, because there are 2^m choices of $A(x)$ and many $\mathcal{O}((m+n)^3)$ algorithms for the above linear system. One way to avoid total enumeration is to use extreme point ranking and linear underestimation [25].

Active-Set Method. A smarter way of enumeration is the active-set method. First, we discuss the inertia of a symmetric matrix since we are dealing with nonconvex QPs. The inertia of symmetric matrix is a three-dimension vector,

$$\text{inertia}(K) = (n_+, n_-, n_0),$$

where n_+ , n_- , and n_0 indicate the numbers of positive, negative, and zero eigenvalues, respectively. This method starts with

a boundary point, and solves a sequence of subproblems, each of which is to find a descent direction and manipulates the active constraints. At step k , the subproblem is to solve a equality-constrained QP, given a fixed boundary point, x_k , as follows:

$$\begin{aligned} \text{Minimize} \quad & f(x_k + s) = \frac{1}{2}s^T Qs + \left(c + Qx_k^T\right)s \\ & + \left(c^T x_k + \frac{1}{2}x_k^T Qx_k\right) \quad (30) \\ \text{s.t.} \quad & A_{\mathcal{I}}(x_k + s) = b_{\mathcal{I}}, \end{aligned}$$

where $A_{\mathcal{I}}$ is a matrix that is composed of linearly independent rows drawn from the active set $\mathcal{I}$. Also the constraint is equivalent to $A_{\mathcal{I}}s = 0$, since $A_{\mathcal{I}}x_k = b_{\mathcal{I}}$. When $s \neq 0$, let α be as follows:

$$\alpha = \min_{i \notin \mathcal{I}} \left\{ \frac{b_i - a_i x_k}{a_i s} \right\}. \quad (31)$$

If $\alpha \geq 1$ and there are no new constraints satisfying $b_i = a_i x_k$, then there is no new constraint becoming active. Otherwise, we should add a new constraint with index i^* corresponding to the minimizer of Equation (31). When $s = 0$, we also need to know the value of dual variable, λ , of the equality-constrained QP subproblem (30). If $\lambda \geq 0$, we stop with the current solution. Otherwise, we drop constraint j^* such that λ_j is the largest for all j in the working set. Inertia controlling is introduced in the nonconvex case. After it was first proposed by Fletcher [26], a lot of variants have been studied. The key point of inertia controlling is that at each step we always select a working set that can control the inertia of the reduced Hessian, $Z^T QZ$ in Equation (29), such that $n_- \leq 1$. Interested reader can refer to the survey paper by Gill *et al.* [27].

Interior Point Method. Interior point method is such a method that traverses a trajectory inside of the feasible region to approach the optimal solution. It is a very efficient method for QP. Instead of considering the format of QP (21), we treat QP in an alternative formulation

$$\begin{aligned}
\text{Minimize} \quad & f(x) = \frac{1}{2}x^T Qx + c^T x \\
\text{s.t.} \quad & Ax = b, \\
& x \geq 0.
\end{aligned} \tag{32}$$

Then add a barrier function in the objective function to eliminate the nonnegativity constraints and make the above QP (32) an equality-constrained nonlinear problem,

$$\begin{aligned}
\text{Minimize} \quad & f(x) = \frac{1}{2}x^T Qx + c^T x + \mu B(x) \\
\text{s.t.} \quad & Ax = b.
\end{aligned} \tag{33}$$

where $\mu > 0$ and usually we use the logarithmic barrier function,

$$B(x) = -\sum_{i=1}^n \ln x_i.$$

The KKT conditions to the barrier problem is as follows:

$$Qx + c - z + A^T \lambda = 0, \tag{34}$$

$$Ax = b, \tag{35}$$

$$x_i z_i = \mu, \quad \forall i = 1, 2, \dots, n, \tag{36}$$

where $z = (z_1, z_2, \dots, z_n)$ and $z_i = \frac{\mu}{x_i}$. Conditions (34)–(36) will coincide with the original KKT conditions (22)–(24) as μ approaches 0. We then use the symbols, x_μ , λ_μ , and z_μ , since they are considered a function of μ in the above system. The trajectory of $(x_\mu, \lambda_\mu, z_\mu)$, as μ approaches 0, is called the *central path*. At each step, there are two main tasks. One is to find an interior point that is close enough to the central path. The other one is to decrease the barrier parameter μ . To calculate a new interior point, two methods are used: line-search-based methods [24] and trust-region-based methods [28]. This is called the primal dual path following method. Also, there exist a variety of interior point methods. In practice, the predictor-corrector primal dual interior point method is very popular. More details about interior point methods can be found in Ye [29].

In general, the active-set methods need a lot of steps to converge, but each step

is comparatively easy. In contrast, interior point methods take fewer steps to converge, but each step is more expensive. In most cases of large-scale problems, usually interior point methods outperform the active set ones. However, with “warm start,” the active-set methods may only need few cheap steps to yield the solution.

GENERAL CONCAVE MINIMIZATION

In this section, we focus on minimizing general concave function $f(x)$ over a polyhedron D . Usually these kinds of problems are referred to as *general concave minimization problems*. Sometimes, the feasible region also takes the form of general compact convex set, which is commonly defined by constraints as $g_i(x) \leq 0$, where $g_i(x)$ is convex.

General concave minimization has a variety of applications. In economics and supply chain management, commodity purchase cost is usually a concave function of purchase quantity, as in the fixed charge, economies of scale assumptions. Hence the objective function is often a concave function.

Sometimes, integer programming problem,

$$\begin{aligned}
\text{Minimize} \quad & f(x) \\
\text{s.t.} \quad & x \in C \cap \{0, 1\}^n,
\end{aligned}$$

is transferred to a concave minimization problem,

$$\begin{aligned}
\text{Minimize} \quad & f(x) + \mu x^T (e - x) \\
\text{s.t.} \quad & x \in C \cap E,
\end{aligned}$$

where C is compact, $E = \{x | 0 \leq x \leq (1, \dots, 1)^T\}$, μ is a sufficiently large number that makes the second term in the objective function dominant and its Hessian is negative semidefinite.

Bilinear programming problem with $Q_{m \times n}$,

$$\begin{aligned}
\text{Minimize} \quad & p^T x + x^T Q y^T + q^T y \\
\text{s.t.} \quad & x \in X, y \in Y,
\end{aligned}$$

is also equivalent to a concave programming problem with piecewise linear objective function because there is no interaction between x and y in the constraints.

In applied mathematics, economics, decision sciences, and engineering, the complementary conditions plays a very important role. It takes the forms as follows:

$$g(x) \geq 0, h(x) \geq 0, g(x)^T h(x) = 0.$$

Finding a solution to the above conditions can be converted to an equivalent concave minimization problem. If $g(\cdot)$ and $h(\cdot)$ are concave on a convex set D , then, whenever it has a solution, it is equivalent to the following concave minimization problem:

$$\begin{aligned} \text{Minimize} \quad & \sum_{i=1}^n \min [g_i(x), h_i(x)] \\ \text{s.t.} \quad & g(x) \geq 0, h(x) \geq 0 \\ & x \in D, \end{aligned}$$

where $\sum_{i=1}^n \min [g_i(x), h_i(x)]$ is concave function because of the concavity of $g(\cdot)$ and $h(\cdot)$, and the fact that $\min[a, b] + \min[c, d] \geq \min[a + c, b + d]$.

By using the concavity of $\ln(\cdot)$ function, multiplicative programs can also be transformed into general concave minimization problems. More and detailed applications can be found in Floudas and Pardalos [30,31]. Not only general concave minimization has many applications, but it also has many solution algorithms. In the following sections, we mainly talk about three important algorithms for general concave minimization: cutting plane algorithm, branch and bound method, and outer and inner approximation algorithm. Interested readers may also refer to the survey paper by Pardalos and Rosen [32].

Cutting Plane Algorithm

A point y is called the γ -extension of x in the direction $d \in \mathcal{R}^n \setminus \{0\}$ with respect to concave function $f(\cdot)$ if $y = x + \theta d$ and $\theta = \min\{\theta_1, \sup\{t | f(x + td) \geq \gamma\}\}$ where θ_1 is a sufficiently large number and γ is a lower bound of $f(x)$.

Let v be a nondegenerate vertex such that $f(v) \geq \gamma$, and $d_1, d_2, \dots, d_n$ be n linear independent edges emanating from v . Suppose that γ is the smallest function value among all function values at feasible points known so far, and $y_1, y_2, \dots, y_n$ are the γ -extensions of vertex $v \in D$ in direction $d_1, d_2, \dots, d_n$ with respect to function $f(\cdot)$. Because $f(\cdot)$ is a concave function, every point x in the simplex $S(v, y_1, y_2, \dots, y_n)$ satisfies that $f(x) \geq \gamma$.

There exists a unique hyperplane containing $y_1, y_2, \dots, y_n$, because $d_1, d_2, \dots, d_n$ are linearly independent. The hyperplane can be defined as

$$H = \{x : e^T Y^{-1} x = 1 + e^T Y^{-1} v\},$$

where $e = (1, 1, \dots, 1)^T$, $\lambda = (\lambda_1, \lambda_2, \dots, \lambda_n)^T$, and $Y = ((y_1 - v), (y_2 - v), \dots, (y_n - v))$. Let $H_+ = \{x : e^T Y^{-1} x \geq 1 + e^T Y^{-1} v\}$ and $H_- = \{x : e^T Y^{-1} x \leq 1 + e^T Y^{-1} v\}$ be two half spaces generated by hyperplane H . By the argument in last paragraph, we know that $f(x) \geq \gamma$ for all $x \in D \cap H_-$. Usually, the hyperplane H is called a *concavity cut*.

The cutting plane algorithm adds a concavity cutting plane at each step until no feasible region can be cut off furthermore. First, set active region $P = D$, and find a vertex v such that $f(v) \geq \gamma$, where γ is an upper bound of the problem. At each iteration, construct a concavity cut H with respect to v , P , and γ . Check if $P \subset H_-$. If true, stop the algorithm. Otherwise, set $P \leftarrow P \cap H_+$. With the new active feasible region, γ, v are recalculated again. Then go to the next iteration. The basic idea is simple, but there are a variety of methods to recalculate γ, v and obtain the concavity cuts based on special properties of different problems.

Branch and Bound Algorithm

Branch and bound algorithm is a widely used technique in not only optimization literature, but also practical optimization software. It is a very powerful method for concave minimization. Usually branch and bound algorithm is finite when only an ϵ -optimal solution is needed. Also convergence speed always depends on ϵ . Many finite exact branch and

bound methods have been proposed since the 1980s[33–35]. Two important parts that differentiate the branch and bound methods from each other are how to partition the space and how to calculate an underestimate of the objective function. Usually there are three ways of partitioning: simplicial, conical, and rectangular subdivisions. Details of partitioning can be found in Horst *et al.* [1]. By taking advantage of the concavity of the objective function, there are many ways to underestimate the objective function value.

Starting with an arbitrary feasible point with upper bound UB, the simplicial algorithm for concave optimization first constructs a simplex, $S_0 \supset D$ and sets the unsolved candidate simplex collection $\mathcal{P} = \{S_0\}$ and solved candidate simplex collection $\mathcal{M} = \{S_0\}$. At each iteration, solve the following problem for all simplices $S(v_0, v_1, \dots, v_n) \in \mathcal{P}$,

$$\begin{aligned} \mu(S) = \text{Minimize} \quad & \sum_{i=0}^n \lambda_i f(v_i) \\ \text{s.t.} \quad & \sum_{i=0}^n \lambda_i v_i \in D, \\ & \sum_{i=0}^n \lambda_i = 1, \quad \lambda_i \geq 0. \end{aligned} \quad (37)$$

Problem (37) yields a lower bound $\mu(S)$ of function $f(\cdot)$ on $S \cap D$, since $f(\cdot)$ is concave. Then set $\text{UB} \leftarrow \min\{\text{UB}, \mu(S), \forall S \in \mathcal{P}\}$, and delete those simplices S from $\mathcal{M}$ such that $\mu(S) \geq \text{UB} - \epsilon$. Select a simplex S^* from $\mathcal{M}$, usually the one which yields the current UB, and subdivide it to at most $n + 1$ simplices by using a point $x^* \in S^*$. Let $\mathcal{P}^*$ be the collection of the new simplices. Update $\mathcal{M} \leftarrow \mathcal{M} \cup \mathcal{P}^* \setminus S^*$, and $\mathcal{P} = \mathcal{P}^*$. When $\mathcal{M} = \emptyset$, stop the algorithm. UB is an ϵ -optimal value. The choice of x^* determines the way the simplex is subdivided. Bisection subdivides the simplex into two parts by using the middle point of its edge. The bisection methods with a positive ϵ has already been proved to be finite. But it does not terminate in finite steps when ϵ equals to 0.

Some modifications will make the above algorithm finite even when $\epsilon = 0$. To ensure

finite convergence, some concavity cuts are added at each iteration. Instead of using D in Equation (37) at every iteration, always use a smaller feasible region D_i , which is constructed by adding new concavity cuts obtained in the last iteration. The finite convergence is achieved only if the global optimum of $f(\cdot)$ is only attained at vertices of D . More details about the new algorithm combining branch and bound and cutting plane and finite convergence conditions can be found in Locatelli and Thoai [36]. Also, other than branch and bound, there are more general methods based on interval analysis, and we refer the readers to other articles [3, 37–45].

Outer and Inner Approximation Algorithms

Outer and inner approximation algorithms are two inherently correlated methods for concave minimization. Both algorithms keep refining the searching region to approximate the feasible region D . Starting with a superset of the feasible region D , the outer approximation shrinks the searching region at each step by adding a new constraint violated by the current optimal vertex. The newly added constraint cuts off some infeasible vertices and introduce new vertices. Usually, vertex enumeration algorithm is used to update the vertex set. However, the inner approximation algorithm works the other way around. It starts with a subset of D or some set whose intersection with D is not empty, and keeps expanding the searching area at each step by adding a new vertex. Both of these two algorithms converge finitely. They can be applied to problem with general convex constraints. For more details of these algorithms, please refer to Horst *et al.* [1].

LINEAR COMPLEMENTARITY PROBLEM, AND MATHEMATICAL PROGRAMS WITH COMPLEMENTARITY CONSTRAINTS

Complementarity appears in a lot of areas such as mathematics, economics, science, engineering, and management. Here, we discuss two important types of problems associated with complementarity, the linear

complementary problem and mathematical programs with complementarity conditions.

Linear Complementarity Problem

Linear complementarity problem (LCP) is a very basic and important class of problems in mathematical optimization area. It is to find a solution z^* to the following system:

$$(Mz + q)^T z = 0, \quad (38)$$

$$Mz + q \geq 0, \quad (39)$$

$$z \geq 0, \quad (40)$$

where M is an $n \times n$ parameter matrix, q is an n -dimensional parameter vector, and z is the variable vector. Usually the complementarity problem, (38)–(40), is denoted by $LCP(q, M)$. LCP unites linear programming, QP, and bimatrix game. The KKT conditions of a linear programming or QP problem is equivalent to an LCP. The KKT conditions of LP $\min\{c^T x | Ax \geq b, x \geq 0\}$ are $(Ax - b)^T y = 0$, $(A^T y - c)^T x = 0$, $A^T y \leq c$, $y \geq 0$, and the primal feasible constraints, where y is the dual variable. By rearranging the terms, the KKT conditions are as follows:

$$\begin{pmatrix} 0 & -A^T \\ A & 0 \end{pmatrix} \begin{bmatrix} x \\ y \end{bmatrix} + \begin{bmatrix} c \\ -b \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = 0, \quad (41)$$

$$\begin{bmatrix} 0 & -A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \geq 0, \quad (42)$$

$$\begin{bmatrix} x \\ y \end{bmatrix} \geq 0. \quad (43)$$

It is an LCP where $M = \begin{bmatrix} 0 & -A^T \\ A & 0 \end{bmatrix}$, $q = \begin{bmatrix} c \\ -b \end{bmatrix}$, and $z = \begin{bmatrix} x \\ y \end{bmatrix}$. Similarly, the KKT conditions of QP (21) with additional constraint $x \geq 0$ are also equivalent to the LCP $\left(\begin{bmatrix} c \\ b \end{bmatrix}, \begin{bmatrix} Q & A^T \\ -A & 0 \end{bmatrix} \right)$.

Let A and B be two $m \times n$ matrices, and e_m be a column vector of m 1's. For every solution, (x', y') , to LCP $\left(\begin{bmatrix} -e_m \\ -e_n \end{bmatrix}, \begin{bmatrix} 0 & A \\ B^T & 0 \end{bmatrix} \right)$, there exists a corresponding Nash equilibrium point, (x^*, y^*) , of the bimatrix game (two persons game) $\Gamma(A, B)$, and vice versa. The relationship is as follows:

$$\begin{bmatrix} x' \\ y' \end{bmatrix} = \begin{bmatrix} \frac{x^*}{(x^*)^T B y^*} \\ \frac{y^*}{(x^*)^T A y^*} \end{bmatrix},$$

$$\begin{bmatrix} x^* \\ y^* \end{bmatrix} = \begin{bmatrix} \frac{x'}{e_m^T x'} \\ \frac{y'}{e_n^T y'} \end{bmatrix}.$$

For more details of the relationship, the interested reader may refer to Murty [46] and Cottle *et al.* [47].

LCP can be solved sometimes as a QP problem,

$$\begin{aligned} &\text{Minimize} && (Mz + q)^T z \\ &\text{s.t.} && Mz + q \geq 0, \\ &&& z \geq 0, \end{aligned} \quad (44)$$

because the objective function is always non-negative with respect to its constraints. With this transformation, we can apply any algorithm discussed before for QP.

However, there exist more specific methods to LCPs, such as Lemke's complementary pivot method and Cottle and Dantzig's principal pivot method [46, 47]. To introduce the pivot algorithms, a little change is needed to the original LCP formulation (38)–(40),

$$wI - Mz = q, \quad (45)$$

$$w^T z = 0, \quad (46)$$

$$z, w \geq 0, \quad (47)$$

where I is an $n \times n$ identity matrix. LCP actually tries to find a complementary cone in $C(M)$ in which vector p lies. Every complementary cone is a positive cone, $Pos(a_1, a_2, \dots, a_n) = \{y | y = \sum_{i=1}^n \alpha_i a_i\}$, formed by n vectors that are drawn from n complementary vector pairs (I_j, M_j) , which are the j th column vectors of matrix I and M , respectively.

Lemke's complementary pivot algorithm works in a way very similar to the simplex algorithm. It starts with an almost complementary feasible basic solution in which only one complementary vector pair is not selected in the basis. Then the algorithm keeps changing the basis by the pivot method. But the entering variable at each step is

always the complementary variable of the dropping variable in the previous step. Usually lexicographic rules are applied to prevent cycling. This algorithm cannot guarantee a feasible solution when the LCP is actually feasible. And the worst possible computation complexity is 2^n . Although it faces these difficulties, this algorithm is widely applied and has a lot of variants.

The generic principal pivot algorithm does not introduce any new artificial variable and only pivots on a variable whose complement is nonpositive. At each step the entering variable is always the complement of the dropping variable. But in the process of this algorithm, the signs of variables may change multiple times. This algorithm is most useful for LCP with M being a P -matrix, a square matrix with every principal minor greater than 0. Cottle and Dantzig's principal pivot algorithm works with major cycles in which there are many substeps. Starting with a complementary basic vector of variables, every major cycle yields an improved complementary basic vector of which at least one more variable is made nonnegative. All the substeps work with almost complementary basic vectors. Cottle and Dantzig's principal pivot algorithm works well for LCP's with M being either a P -matrix or a PSD matrix. According to different special structures of M in LCP, there exist many polynomial bounded algorithms. We refer the reader to Murty [46] and Cottle *et al.* [47] for more details.

LCP is only a special case of the family of complementarity problems (CPs). Nonlinear complementarity problem (NCP) is also a very popular topic, which includes a nonlinear transformation instead of the affine transformation. For a nonlinear mapping $F : \mathbb{R}^n \mapsto \mathbb{R}^n$, $\text{NCP}(F)$ is to find a vector x such that

$$\begin{aligned} x^T F(x) &= 0, \\ F(x) &\geq 0, \quad x \geq 0. \end{aligned}$$

In addition, the mixed linear and nonlinear complementarity problems also draw a lot of attention, both being special cases of the generalized complementarity problems. A broader topic is the variational inequality

(VI), which is usually denoted by $\text{VI}(K, F)$, where $K \subseteq \mathbb{R}^n$, $F : K \mapsto \mathbb{R}^n$. CP and VI comprise a very important mathematical programming branch and include a lot of applications. More comprehensive discussion can be found in Facchinei and Pang [48].

Mathematical Program with Complementarity Constraints

Mathematical program with complementarity constraints, usually abbreviated as MPCC, is a very important and useful type of problem that appears in literature. MPCC, as its name suggests, is an optimization problem where some of its constraints are formulated as complementarity problems. Generally, it has the following form:

$$\begin{aligned} \text{Minimize} \quad & f(x) \\ \text{s.t.} \quad & F_i(x)G_i(x) = 0, \quad i = 1, \dots, m, \\ & F_i(x) \geq 0, \quad i = 1, \dots, m, \\ & G_i(x) \geq 0, \quad i = 1, \dots, m, \\ & g(x) \leq 0, \\ & h(x) = 0. \end{aligned}$$

MPCC is a very difficult problem that involves nonconvexity and nonsmoothness. However, many useful algorithms have been used to solve MPCC, such as branch and bound method, complementary pivot method, active-set method, sequential quadratic programming method, and interior point method [48–50].

Branch and bound method is widely used for MPCC. Its idea is very simple but powerful. Because complementarity constraints are intrinsically combinatorial, MPCC can be solved by using enumeration methods. Total enumeration always takes a lot of time. A better way to avoid this is to branch and bound. At the initial node, all the complementarity constraints are dropped. At any other node of the binary branch and bound tree, one more complementarity constraint is added in such a way that one branch emanating from the node includes an additional constraint $F_i(x) = 0$, the other with $G_i(x) = 0$. Then a lower bound is computed with additional

constraints as above, but without any complementarity constraint. The upper bound can be achieved by solving the current relaxed problem by arbitrarily choosing any of the complementarity, $F_i(x)$ or $G_i(x)$, to be zero for all the undetermined complementarity constraints. The difference when compared with standard branch and bound method is that both lower bound and upper bound are generated at each node. Interested reader may refer to Scheel and Scholtes [50] for more details about the properties of MPCC.

Also bilevel programming problems are often reformulated as MPCC because of the KKT conditions of the inner optimization problem. Interested readers may want to refer to Dempe [51] and Colson *et al.* [52] for more comprehensive details. Including integer variables into these problems would make them much harder. Interested readers may refer to DeNegre and Ralphs [53], Moore and Bard [54], Wen and Yang [55] for some algorithms to solve the integer bilevel programming problems. Bilevel programming belongs to hierarchical programming problems, where there is a hierarchy of decisions. A variety of theories, problems, algorithms, and applications of this type can be found in Migdalas *et al.* [56]. On the other hand, MPCC is a special case of mathematical programs with equilibrium constraints (MPEC), where complementarity conditions are replaced by their extension, namely, variational inequalities. For more details about MPEC, the interested reader may refer to Luo *et al.* [49].

DISCRETE OPTIMIZATION PROBLEMS

Many 0-1 integer programming problems could be reduced to continuous optimization problems. This reduction permits us to employ the techniques in global optimization to these problems. Consider the following 0-1 integer programming problem:

$$\text{Minimize } c^T x \quad (48)$$

$$\text{s.t. } Ax \leq b, \quad (49)$$

$$x_i \in \{0, 1\}, i = 1, \dots, n. \quad (50)$$

The above problem is equivalent to the concave minimization problem:

$$\text{Minimize } c^T x + \mu x^T(e - x) \quad (51)$$

$$\text{s.t. } Ax \leq b, \quad (52)$$

$$0 \leq x \leq e. \quad (53)$$

For a sufficiently large value of μ , at optimality $x^T(e - x) = 0$. Similar reduction for 0-1 integer programming problems are possible. We discuss such formulations for some combinatorial optimization problem namely, the clique problem, the satisfiability problem, and quadratic assignment problem in this section.

Satisfiability Problem (SAT)

The satisfiability (SAT) problem could be stated as follows: Given a set of literals $L = \{x_1, x_2, \dots, x_m\}$ and a collection of clauses $C = \{c_1, c_2, \dots, c_n\}$ over L , is there a truth assignment of L that simultaneously satisfies all clauses of C ? The problem could be expressed in the conjunctive normal form (CNF)

$$\bigwedge_{i=1}^n c_i = \bigwedge_{i=1}^n \left(\bigvee_{j=1}^{m_i} l_{ij} \right), \quad (54)$$

where $l_{ij} \in \{x_i, \bar{x}_i\}$ is the literal j in clause i . Given a CNF, we define a new function $f: \mathcal{R}^m \rightarrow \mathcal{R}$ and provide the following global optimization problem that is equivalent to SAT:

$$\text{Minimize } f(y) \quad (55)$$

$$\text{s.t. } y \in \mathcal{R}^m, \quad (56)$$

where

$$f(y) = \sum_{i=1}^n \prod_{j=1}^{m_i} q_{ij}(y_j), \quad (57)$$

$$q_{ij}(y_j) = \begin{cases} (y_j - 1)^{2p} & \text{if } x_j \text{ is in } c_i, \\ (y_j + 1)^{2p} & \text{if } \bar{x}_j \text{ is in } c_i, \\ 1 & \text{otherwise,} \end{cases} \quad (58)$$

where p is a positive integer and $y_j = 2x_j - 1$.

Theorem 6. *There is a satisfiable truth assignment to the CNF if and only if $f(y) = 0$ for the corresponding $y \in \{-1, 1\}^m$.*

The discrete SAT problem is transformed to the above continuous global optimization problem and there is equivalence between the optimal solution of the global optimization problem and the truth assignment for the satisfiability problem. A more comprehensive survey on satisfiability problem could be found in Du and Pardalos [57]. Another article on global optimization [58] also discusses the SAT problem.

Quadratic Assignment Problem

In a quadratic assignment problem, we need to assign n facilities to n locations. We are given two $n \times n$ matrices A and B that provides the flow of material between facilities and distance between the locations, respectively. We denote the elements of matrices A and B as $a_{ij}, i, j = 1, 2, \dots, n$ and $b_{ij}, i, j = 1, 2, \dots, n$, respectively. The minimum cost assignment problem could be formulated as follows:

$$\text{Minimize} \quad \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n \sum_{l=1}^n a_{ik} b_{jl} x_{ij} x_{kl} \quad (59)$$

$$\text{s.t.} \quad \sum_{i=1}^n x_{ij} = 1, j = 1, 2, \dots, n, \quad (60)$$

$$\sum_{j=1}^n x_{ij} = 1, i = 1, 2, \dots, n, \quad (61)$$

$$x \in \{0, 1\}^n, \quad (62)$$

where x_{ij} is the binary variable indicating whether facility i has been assigned to location j or not. The above 0-1 quadratic integer programming problem could be reduced to the following concave programming problem:

$$\text{Minimize} \quad x^T Q x \quad (63)$$

$$\text{s.t.} \quad \sum_{i=1}^n x_{ij} = 1, j = 1, 2, \dots, n, \quad (64)$$

$$\sum_{j=1}^n x_{ij} = 1, i = 1, 2, \dots, n, \quad (65)$$

$$x \geq 0, \quad (66)$$

where $Q = S - \alpha I, \alpha > \|S\|_\infty$ and S is the $n^2 \times n^2$ matrix with the entries $a_{ij} b_{kl}$. The rows of S are defined by i and j fixed and the columns with k and l fixed. The problem was well studied by Lawler [59] and the reader may refer this for a more comprehensive review on the quadratic assignment problem.

Maximum Clique Problem

The maximum clique problem is to determine a subgraph of maximum size in graph $G = (V, E)$, where G is a simple undirected graph and V and E are its corresponding vertex and edge set. Let A_G be the adjacency matrix of the graph G . Then the maximum clique problem could be formulated as follows:

$$\text{Minimize} \quad f_G(x) = \sum_{(ij) \in E} x_i x_j = x^T A_G x \quad (67)$$

$$\text{s.t.} \quad x \in X, \quad (68)$$

where $X = \{x : \sum_i x_i = 1, x_i \geq 0, i = 1, 2, \dots, n\}$. The following theorem provides the equivalence between the optimal solution of the above concave programming problem and the maximum clique in graph G .

Theorem 7. *If $\alpha = \max\{f_G(x) : x \in X\}$ then the maximum clique C in graph G is of size $\frac{1}{(1-2\alpha)}$. This is attained with $x_i = \frac{1}{k}$ if $i \in C$ and $x_i = 0$ if $i \notin C$.*

The maximum independent set problem, which seeks the maximum empty subgraph within a given graph, could be modeled as follows:

$$\text{Maximize} \quad x^T A x \quad (69)$$

$$\text{s.t.} \quad x \in \{0, 1\}^n, \quad (70)$$

where the binary variable x_i indicating the presence of vertex i in the optimal solution and matrix $A = I_{n \times n} - A_G$.

The maximum cut problem in a graph $G(V, E)$ with a weight function on the edge set $w : E \rightarrow \mathbb{R}$, seeks a partition of the vertex set V into S and $\bar{S}$ such that the cut set formed by the partition is maximum ($\max cut(S, \bar{S})$). This could be modeled as a quadratic $\{-1, 1\}$ -variable problem as follows.

$$\text{Maximize} \quad \frac{1}{2} \sum_{i,j \in V} w_{ij} (1 - x_i x_j) \quad (71)$$

$$\text{s.t.} \quad x \in \{-1, 1\}^n, \quad (72)$$

where x_i takes the value -1 if the vertex i is in set S and value 1 if it is in set $\bar{S}$ in the optimal solution.

CONCLUSIONS

Global optimization methods are usually NP-hard problems. There are exact and heuristic methods available to solve these problems. In this article, we discussed some deterministic methods to solve various global optimization methods. More specifically, we discussed about QP, DC, optimization and relations between global and discrete optimization problems. We provided some theoretical results relating them to specific problems and the algorithmic methods that were developed based on the theoretical results. This article focuses on deterministic and exact methods in global optimization and for stochastic and metaheuristic based methods we refer the readers to the following articles [60–65].

DIFFERENT FORMATS FOR THE COMMUNICATION OF RISKS: VERBAL, NUMERICAL, AND GRAPHICAL FORMATS

INTRODUCTION

In our daily life we encounter many risks. In order to make informed decisions an adequate understanding of the risks is necessary, whether these are financial risks for investment decisions, health risks, or treatment risks such as surgery. Unfortunately, people have great difficulty in adequately understanding risks. Besides limited cognitive skills, this may also be due to a suboptimal presentation of the risks.

Risk is often defined as the probability that a negative event will happen, or the probability of a hazard occurring that will cause a harmful effect. Risk is measured uncertainty or a quantification of uncertainty. The quantitative nature and the uncertainty that risks convey both add to the difficulty in understanding, as they make the information inherently abstract. Information about the quantitative aspect of risks can be presented in many different ways (Table 1). Risks can be described in verbal terms (“a high risk”), by means of numerical estimates (“a risk of 7%”), or they can be represented graphically in diagrams or charts. These different ways of presenting risk information affect how people perceive risks and can influence the decisions they make. Some risk representations may be better suited to inform people about a single risk, whereas others may provide more clarity when

complex trade-offs need to be made. In this article, we will discuss the characteristics of different formats for risk communication and the evidence about their suitability for risk communication in different situations. We will focus on verbal terms for risks, the use of numerical formats, and the effects of graphical risk representations. We will illustrate this with examples from the domain of health risks. We end with some general recommendations for risk communication.

USING VERBAL TERMS TO EXPRESS PROBABILITIES

In daily life, verbal terms are probably the most commonly used mode for communicating information about risks. Physicians often express the probability of their diagnosis or the risk of treatment in verbal probability terms, for instance, by stating: “Your headache is *probably* caused by stress; it is *very unlikely* that it indicates a tumor and it will *almost certainly* get better in a week.” At first sight, this seems a clear way of communicating probability information as the terms have a very intuitive feel and meaning attached to them. Although verbal terms appear very meaningful, it is often not clear how they should be interpreted exactly. Many studies show that people differ greatly in the interpretation and use of verbal labels [1–5]. These differences do not just reflect differences in knowledge or experience, as they have been found to exist between experienced physicians when judging cases within their own domain [1,6]. There is no consensus, for example, on where the numerical threshold should be drawn between risks that are classified as “high” and “low.” Timmermans *et al.* [1] found that terms such as “extremely rare” had a wide range of numerical interpretations, that is, from 0.001% to 10%. Similarly, the term “very likely” was associated with probabilities ranging from 40% to 100% (Fig. 1). Using verbal terms to express uncertainty can thus result in ambiguous messages.

Table 1. Common Formats for Communicating Risks

Population diagrams
Miscellaneous (mixtures)

As a risk format, verbal probability terms reflect an interpretation of the risk size and not a factual statement. Individuals differ in how they interpret risks and which verbal term best reflects a certain risk. Moreover, several aspects have been found to affect the interpretation of verbal terms. Verbal risk labels are attributed a higher probability when the outcome it refers to is perceived to be relatively more common or when the consequences are more severe [8,9]. For instance, the probability conveyed by the

phrase “It is likely that you will get influenza this year” is seen as involving a higher quantitative risk than the phrase “It is likely that you will get pneumonia this year”. Mapes [9] found that less serious “rare” side effects of antihistamines were deemed more likely than more serious “rare” side effects of beta-blockers. Verbal probability terms thus reflect a personal interpretation of the perceived absolute probability, the relative probability, and the severity of the potential outcome that the risk term refers to. Verbal terms can thereby be very rich in meaning, but this meaning is multidimensional, and recipients may not always share the same interpretation as the person giving the information [10–12]. Difficulties may particularly arise when individuals interpret a verbal risk term as reflecting the severity of, for example, a medical condition instead of the probability. In this regard, Gurmankin *et al.* [13,14] found that many patients thought that the physician attempted to downplay cancer risks when they were described in verbal terms. In an attempt to “correct” this feeling, the patients subsequently perceived the risks as higher than they really were. Thus, in addition to large interindividual differences in the numerical interpretation of verbal terms of uncertainty, there are also large intersituational differences. The observed ambiguity of verbal terms often

Figure 1. The numerical interpretation of verbal terms (used in patient cases) of internists, surgeons, residents in internal medicine and surgery, and interns. The vertical lines represent the means and the horizontal lines depict the range of estimates [7].

lead to miscommunications, suggesting that it would be better if verbal expressions are replaced by more precise and clearer numerical terms.

The appealing simplicity and common use of verbal probability terms has led to several initiatives exploring the standardized use of verbal risk terms to express specific numerical probabilities. The EU has, for instance, proposed using a list of verbal risk descriptors that each have a predefined and limited range of associated probabilities they are to convey [15,16]. In this way, it was expected that the rich meaning of verbal terms could be retained, while the large range in interpretations could be restricted. Such standardizations, however, have repeatedly proven to be impractical, because the range of numerical values is too variable and sensitive to the specific situation. Subsequently, the use of standardized verbal labels probably creates more confusion than it resolves.

Whereas their ambiguity may limit the usefulness of verbal risk terms as a universal standard for risk communication, their rich meaning can be practical when providing guidance in interpretation is considered more important than providing clarity over the exact risk size. Sometimes epidemiological data may be absent or too unspecific to provide exact risk estimates in a situation. Less accurate, but meaningful, verbal descriptions may then be most appropriate. In other situations, verbal risk terms may be useful as they allow physicians to incorporate persuasive meanings when patients clearly need them. Physicians may, for instance, want to reassure patients who seem unduly worried, or to convince patients about the riskiness of certain choices. Verbal expressions of probability may then give a direction to how a patient or consumer should interpret the risks [17]. In each situation, the apparent elegance of a compact verbal risk term must be traded off against a more precise, but perhaps less familiar numerical expression.

In conclusion, on the one hand, using verbal terms instead of numbers leads to a loss of information, because the exact meaning is not clear. On the other hand, by using verbal expressions additional meaning beyond probability is communicated. This might explain

Table 2. Pros and Cons of Verbal Risk Formats

Verbal Risk Format	
Pros	Cons
Seemingly simple and clear	Prone to miscommunication
Part of everyday language	Large variation in interpretation between individuals and between situations
Allows for affective message	Less trustworthy
May give additional meaning and guidance for interpretation	Imprecise and vague
Intuitive appeal	

the finding that the majority of people prefer to receive probabilistic or uncertain information in numerical terms, but like to use verbal terms when communicating this information themselves [18]. The speaker intends to communicate more information than the probability of an event, which might be more than the receiver expects. See Table 2 for a list of pros and cons of using verbal terms for risks.

USING NUMBERS TO EXPRESS PROBABILITIES

The quantitative nature of risk information makes numerical risk formats a logical tool for risk communication. Using numbers allows one to be specific, exact, and factual about the absolute and relative size of risks. In many situations where risks are communicated, individuals have the option to choose between two or more alternatives. These alternatives can, for instance, include different types of treatment or changing one's behavior versus maintaining a status quo. As the risks and benefits of the alternatives need to be weighed against each other, the degree to which these risks differ needs to be clarified. Within the realm of evidence-based medicine and informed decision making, such factuality and precision are appealing features of numerical risk formats. In

addition, when asked, many persons indicate that they trust numerical information more compared to verbal terms when they are informed about risks [13,14]. Unfortunately, laypeople often have great difficulty understanding and using numerical estimates of risk [19].

Although, the communication of risks in numbers appears to contribute to a more transparent and neutral communication process, one study shows that the interpretation of numerical risks is not straightforward [20]. Many people have a limited intuitive feel for numerical information. This may be particularly problematic if the risks are unfamiliar, as is commonly the case in the medical domain. There are various numerical formats that can be used to convey risk information. The most commonly used formats use a standardized scale like percentages (0–100%) or probabilities (0–1). Other formats like relative frequencies (x out of 100 or 1 out of x) and odds (x to 1) do not have a standardized scale.

Communicating Absolute Risks: Odds, Probabilities, Percentages and Frequencies

The literature on risk communication about the effects of different risk formats focuses primarily on the use of percentages and frequencies. The few studies [21] which discussed odds show that the use of odds for risk communication to professionals or the public does not seem ideal.

Risk perceptions may be significantly different, depending on the numerical format used. A general characteristic to explain differences in the interpretation of numerical risk formats is the degree to which the format reflects the occurrence of concrete and imaginable events. Communicating a risk as a true probability statement (e.g., “a chance of 0.10” or “a chance of 10% that event Y happens”) leads to poorer comprehension than when the risk statement explicitly states which sample is at risk (e.g., “out of a 100 patients who undergo procedure X, event Y will happen to 10” [22,23]. A reason is that in the latter statement the reference class, that is the population at risk, is clarified. Further, several studies have observed that a format that expresses risks as frequencies

yields higher perceived risks than when the risk is expressed as a percentage. Slovic *et al.* [24], for instance, found that if the risk of a psychiatric patient committing an act of violence was presented as a frequency (e.g., “20 out of 100 patients similar to this one commit an act of violence”) about twice as many psychiatrists (40% vs. 20%) refused to release the patient from care as opposed to when the risk was presented as a percentage (i.e., “a 20% chance”). Although this is supported by some studies [25–28], other studies failed to find a difference [13,14,21,29,30], thus indicating that the effect may not always be profound. Overall, frequency formats appear to at least have the potential of eliciting stronger effects on risk perception than percentages when single risks are communicated. The common hypothesized explanation for these findings is that frequencies are better at evoking an image of the risk since they refer to concrete numbers of events, whereas percentages primarily represent a more abstract and normalized proportion on a continuous scale. These explanations reflect that frequencies may be perceived as more meaningful, which is an important property in view of effective risk communication.

The explanation that the use of concrete numbers in risk communication stimulates intuitive risk perception may also explain why probabilities proper are hardly ever used in risk communication. As probabilities are standardized on a scale of 0–1, they do not directly refer to real events. Similarly, the beneficial effect of using real numbers would advise against the use of numbers with decimals when communicating risks. This may lend further support for the use of frequencies, as they allow using real numbers when risks are lower than 1%.

While it is difficult for many people to understand single risks, conditional risks are even harder to understand. Conditional risks are difficult to comprehend because they are risks that depend on another outcome. For example, when a rather young woman with a low prior risk on breast cancer tests positive on a mammogram, she still has a low chance of having breast cancer. The posterior probability of having cancer with a positive test result depends on the accuracy of the test,

as well as on the prior probability. This is easier to understand if the probabilities are presented in natural frequencies [22,31–33]. Because such sampling of frequencies preserves base rates, the predictive value is clear without the need for further calculations. This method of using one sample to illustrate the diverse possibilities is considered to reflect how people observe risks in daily life and this mode of risk communication has subsequently been dubbed using “natural frequencies.”

Communicating Absolute Risks: Different Formats for Frequencies

While using frequencies may generally be more concrete, they comprise a diverse range of formats that do not necessarily have the same effects. A first distinction between different frequency formats is that between using a fixed numerator (1 out of x) and using a fixed denominator (e.g., x out of 100 or x out of 1000). Studies that looked at differences between these two formats reported contrasting findings. In line with the explanation that risks appear higher when it is easier to imagine them, that is, when they are more concrete, a few studies report that risks are perceived as higher when frequency formats use smaller denominators [34,35]. These findings suggest that, because it is easier to visualize a group of 10 persons of whom 1 is ill than it is to imagine a group of 1000 persons of whom 100 are ill, the former risk appears higher. Other studies, however, found that risks are perceived as higher when larger denominators are used, for example, 10 in 100 is perceived as larger than 1 in 10 [36]. People might be focusing mainly on the nominator *or* the denominator without assessing the size of the risk. While it thus may be important for risk perception to use a numerical format that refers to concrete events, more complex situations would account for people’s tendency to process information in the simplest and fastest way.

Other Numerical Formats: Relative Risk, Number Needed to Treat

As described earlier, comparing risks for, for example, treatment decisions requires

a presentation of absolute risks that allows for easy and intuitive comparisons (e.g., frequencies with the same denominator). The size of the difference between the risks is often explicitly communicated in order to clarify its importance for the decision. Typically, this difference can be presented as a relative risk or as an absolute risk reduction. The latter can be presented as just the absolute difference in risks (for example: “a risk reduction of 2%”), or as its reciprocal via the “number needed to treat” (for example: 50 patients need to be treated to prevent 1 case). In a large systematic review, Covey [37] found strong evidence that differences between risks are generally considered to be greater when they are expressed as relative risks instead of absolute differences between incidence rates, and that subsequently more patients agreed to treatment. This effect was particularly strong when the word “relative” was not explicitly mentioned when the risk reduction was communicated. For example, a 30% reduction of the risk of developing heart disease is perceived as much larger than an absolute reduction from 3% to 2%. So while relative risk reductions can be persuasive, they also easily create misperceptions about the true effects of a treatment or change in lifestyle, which may be at odds with informed decision making [38]. It is therefore commonly advised to present relative risk reductions only when the absolute risks are also clear. This clarifies the perceived effectiveness of treatment.

As for presenting absolute risks reductions, the “number needed to treat (or harm)” (NNT; i.e., the number of patients that need to be treated for one to benefit) has been advocated by some as a good and simple tool for communicating the effectiveness of a treatment [39–42]. However, there is no real evidence that suggests that people’s risk perceptions or decision-making benefits from using the NNT format as opposed to communicating the absolute risk reduction.

In conclusion, the studies on numerical risk formats show that two generic characteristics are important for optimizing risk perceptions and decision making. First, more concrete formats seem to evoke more meaningful risk images, which improves risk

Table 3. Pros and Cons of Numerical Risk Formats

Numerical Risk Formats	Pros	Cons
	Exact and precise Factual	Difficult to understand Not easy to imagine, abstract
	More trustworthy Transparent and neutral	
<i>Percentages</i>	When > 1% clear, in particular when reference class is made explicit Familiar format	Not easy to imagine when < 1%
<i>Frequencies</i>	More concrete (refer to real events/people) Easier for conditional risks	
1 of X	Easier to visualize, more concrete	More difficult for comparing risks
X of 100	Easier for comparing risk	Harder to imagine because larger group
<i>Odds, probabilities</i>	Useful for scientific communication	Difficult to imagine, less concrete Difficult to understand

perception. Therefore, if the size of single risks is clear, it seems advisable to use a frequency format. Lower denominators (e.g., “1 in X ”) may then yield the most concrete risk image, and numbers with decimals should be avoided. Second, in more complex situations, it is particularly important to minimize the complexity of risk information and to present risks so that errors are prevented. This means, for instance, that the risks that are most relevant for the specific decision need to be made explicit and that computations should be avoided. Further, the format needs to accommodate the task that is needed for decision making. If risks need to be compared or added, it is important to use either percentages or frequencies that share the same denominator. When risk estimates concern nested numbers, for example, joint probabilities or conditional risks, it may be particularly relevant to use one confined sample of persons or events to illustrate all possible outcomes, as this reduces cognitive effort. When presenting relative risk reductions, it is advisable to also present the absolute risks. This clarifies the perceived effectiveness of, for example,

treatments. See Table 3 for a listing of the pros and cons of using numerical risk formats.

USING GRAPHICS TO EXPRESS PROBABILITIES

Given the vagueness of verbal terms and the difficulty of numerical formats, alternative formats for risk communication have been explored. The use of visual displays or graphical formats is particularly popular in this respect. In their extensive review, Lipkus and Holland [43] describe three potential benefits of using graphical formats: (i) they allow the illustration of complex causal relations, trends in time, or quantitative part-to-whole proportions; (ii) they can evoke specific mathematical operations such as comparisons without cognitive effort; (iii) they are vivid and grab the attention so that they can be used to underline specific messages. Because of these assumed benefits, graphical formats are often used in daily practice. However, evidence about the degree to which they are really helpful in decision making is not unequivocally strong.

Graphical risk formats typically reflect the quantitative nature of risk information. The most common formats present these quantities either by the relative size on a standardized scale, for instance, as a bar chart, or by absolute and discrete numbers of icons that represent events, for example, in a population diagram. These specific features affect their suitability for conveying different types of information and as a result their effect may differ per decision situation. On a basic level, it has been found that when processing visual information, people are more sensitive to differences in height and areas than to differences in the angles between lines. Feldman-Stewart *et al.* [44], found that vertical bars were superior to pie charts, horizontal bars, or numbers, with respect to the accuracy and time efficiency when people had to compare two risks. This suggests that bar charts or similarly designed visual formats would be suitable for highlighting differences when several alternatives need to be compared. Population diagrams refer to discrete events and may make them, thus, more suitable for presenting information about a limited number of single risks.

Timmermans *et al.* [30] found that illustrating a single risk visually in a population diagram yielded stronger affective reactions to the risk, while comprehension was not affected. Such a stronger affective impact of risk information, possibly reflecting a higher awareness of the risks, has been observed more often. Others [45–47] found that participants behaved more risk averse when risks of accidents were illustrated visually as icons (stick figures, or other symbols to represent the number of affected persons) compared with numerical risk information only. Timmermans *et al.* [1] found that presenting risk in a population diagram made fewer patients opt for surgery (i.e., the more risky option) as opposed to watchful waiting than when risks were presented numerically. Graphical risk information may thus increase the saliency of risk information, especially when it concerns single risks and the format illustrates the risk in a discrete manner.

Apart from grabbing the attention, it is less clear whether visual information aids

decision making in more complex situations. Fagerlin *et al.* [48] did find that the use of population diagrams prevented people from basing decisions on anecdotal information more effectively than using numerical risk formats. However, in the study by Timmermans *et al.* [1] the aversion to surgical risks when a population diagram was shown made more people opt for watchful waiting despite the fact that this was the option with lower life expectancy. Other studies [27,29,49] found no effects of using bar charts or population diagrams on decision making. There is, thus, very limited evidence that suggests that visual risk formats substantially aid decision making.

The translation of quantitative risk information into a visually meaningful representation may look very different depending on the decision situation. This makes it difficult to merge findings from different studies and to assess the true value of visual risk formats. There is limited evidence as to which risk representation and which visual format may be most effective under which circumstances. As mentioned, the discrete nature of population diagrams may, in theory, make them more useful for communicating single risks than for more complex situations. However, their practical use may sometimes be limited. Risks below 1% would require diagrams that describe populations of 1000 or more persons or events, and this may take up a disproportional amount of space in a leaflet. Additionally, when various risks are involved and complex decisions are at hand, population diagrams allow little room for summarizing data and can easily become complicated. It may seem preferable to then use visual displays that can summarize data, such as bar charts, as they allow simplification of complex comparisons. Stacked bar charts can, for instance, represent total risks that consist of different outcomes and illustrate differences between several alternatives more concisely. Waters *et al.* [50] showed that such presentations may yield small benefits in terms of accuracy as compared to presenting only numbers.

In addition to bar charts, other summarizing visual formats are possible, such as

thermometer scales or survival curves or even 3D graphs. Whereas such formats may have appeal and could grab attention, there are few to no studies that have assessed their benefit or usefulness. Some studies did find that fairly complicated graphs, such as survival curves, are not easily understood, even after training [51]. This would limit the use of these complex graphs, as it may induce wrong interpretations.

In conclusion, in terms of the true benefits of graphical formats, the increased awareness of the risk information may be the most important one. In addition, visual displays can look appealing, and many patients indicate that they find them useful and appreciate it when they are used [43]. These aspects and effects may be important, given the tendency of people to ignore risk information in decision making. Visual formats may then be particularly useful when the primary purpose of risk communication is to increase awareness of risks. There is, however, limited evidence until date that suggests that graphical formats substantially improve understanding and aid decision making. See Table 4 for a listing of pros and cons of using graphical formats for risks.

Table 4. Pros and Cons of Graphical Risk Formats

Graphical Formats	
Pros	Cons
Effective in summarizing a lot of information	Difficult to determine which graphical format is best
Useful for clarifying relationships of risks (e.g., time trends)	No evidence for positive effect on understanding or informed decision making, some graphical formats are very difficult
Might reduce cognitive effort in processing risk information	Population diagrams not insightful for very small risks (e.g., 1 out of 1 000)
More vivid and draws one's attention	Might have an inappropriate effect by emphasizing information

GENERAL RECOMMENDATIONS FOR RISK COMMUNICATION

Based on the evidence about the effectiveness of different formats for risk communication, the following recommendations can be given. Risk formats should preferably be numerical (i.e., exact), as simple as possible (i.e., reducing cognitive complexity) and as concrete as possible (i.e., easy to imagine). In general, people prefer precise, numerical risk information, even though this might be difficult to comprehend. Further, it is important to reduce the cognitive complexity of the information because if the information is too complex people resort to heuristic processing, which sometimes leads to suboptimal decisions. It is important that risk information is easy to imagine so that people find the risk applicable to themselves and are more likely, for instance, to change their behavior. The 10 general recommendations for effective risk communication can be summarized as follows: *Be exact, make it concrete, and keep it simple!* Therefore, for the communication of the probability or quantitative aspect of risks, this means:

Be exact

1. *Risks should be quantified if possible.* Providing verbal descriptions only (e.g., “a very big chance”) or using colors (“you belong to the red group”) is not sufficient.
2. *When verbal terms* are used to express probabilities, be as neutral as possible and be aware of its goal when using verbal terms (e.g., to reassure a patient).

Make it concrete

3. *Do not use expressions of probability that do not refer to concrete events.* In other words: do not use percentages smaller than 1%, do not use probabilities (0–1), and do not use frequencies or percentages with decimals.
4. *Use frequencies if possible*, for example, “15 out of 100 people like you will suffer from heart disease within 10 years”, *not* “there is a

chance of 15% that you will suffer from heart disease within 10 years.”

5. *The reference group should be made explicit*, and when more than one risk is communicated the same reference group should be used. It should be clear to which group of people or events the probability refers, for example, “80% of the people with this disease will get better”, *not* “there is a chance of 80% of getting better.”
 6. *Use the smallest possible denominator*, when using frequencies to express single risks, for example, “1 out of 30 people will develop cancer”; *not* “3 out of 100 people will develop cancer”.
 7. *Shorter time frames* are preferred over longer time frames (five-year risk and not lifetime risk). However, this may lead to underestimating longer-term risks.
- Keep it simple
8. *Use the same format* when communicating several risks. Do not mix frequencies and percentages, for example, do *not* say “there is a 5% chance on mortality, and 10 out of 100 people report severe side effects”; instead, say “5 out of 100 people die, and 10 out of 100 people report severe side effects.”
 9. *Keep the denominator constant*, if several risks are given. It is easier for people to compare these risks, for example, “80 out of 100 people will get better, 4 out of 100 will experience side effects”; *not* “80 out of 100 people will get better, 1 out of 25 will experience side effects”.
 10. *The use of graphics* might be a good idea, although there is insufficient evidence that this improves people’s comprehension and decision making. It has been shown to have a larger affective impact than numerical information and may thus be used to motivate people to, for example, change their health behavior.

DIFFERENTIAL GAMES

NGO VAN LONG
Department of Economics,
McGill University,
Montreal, Quebec,
Canada

Differential games (DG) are dynamic games that take place in continuous-time. The theory of differential games is a natural extension of optimal control theory (or its predecessor, the calculus of variations) and is a notable example of cross fertilization between game theory and theory of dynamic optimization. This theory provides a powerful tool of analysis in operations research, management science, and economics. Ref. 1 gives comprehensive exposition of the theory and techniques, including applications in various fields. As a subfield of game theory, the theory of differential games adds to the classical game theory a more structured dynamic dimension and provides well-developed methods of solving an important class of dynamical game-theoretic problems. As pointed out in Ref. 1, this theory owes much to the pioneering work of Isaacs in the 1950s.

BASIC FEATURES OF DIFFERENTIAL GAME

In optimal control theory [2], a single decision maker faces a changing environment represented by a vector of m state variables, denoted by $x(t) \in X$.

He chooses a time path of his vector of control variables $u(t)$ to maximize his payoff which is the integral of a stream of discounted benefits $b(t)$ plus the discounted value of a terminal scrap value $S(x_T, T)$ where T denotes the terminal time. The benefit $b(t)$ is a function of the state variables, the control variables, $b(t) = B(x(t), u(t), t)$. The evolution of the state variables is described by a system of differential equations, with given initial conditions.

Let $r > 0$ be the decision maker's discount rate. The payoff of the decision maker is

$$W = \int_0^T \exp(-rt) B(x(t), u(t), t) dt \\ + \exp(-rT) S(x_T, T).$$

The control vector must belong to a specified set U . The terminal vector x_T may be fixed, or free, or restricted to a specified set X_T .

In a differential game, there are n decision makers who typically do not cooperate with each other. We call them the players of the game. Let $N \equiv \{1, 2, \dots, n\}$ denote the set of players. Player i has a vector of control variables u_i . The benefit function of player i generally depends not only on x and u_i but also on the control variables of other players:

$$b_i(t) = B_i(x(t), u_1(t), \dots, u_n(t), t).$$

The evolution of the state variable x_k for $k = 1, 2, \dots, m$ generally depends on the actions of all the players:

$$\frac{dx_k}{dt} = f_k(x, u, t).$$

The initial condition is $x_k = x_0$.

In vector notation,

$$\frac{dx}{dt} = f(x, u, t) \text{ with initial condition } x(0) = x_0.$$

The payoff of decision maker i is

$$W_i = \int_0^T \exp(-r_i t) B_i(x, u_1, u_2, \dots, u_n, t) dt \\ + \exp(-r_i T) S_i(x_T, T).$$

In a noncooperative differential game, each player i takes the strategies of other players as given, and chooses a time path for his control vector u_i to maximize his payoff. The simplest class of strategies is that of "open-loop strategies," and

the corresponding equilibrium concept is open-loop Nash equilibrium.

OPEN-LOOP STRATEGIES AND OPEN-LOOP NASH EQUILIBRIUM

An open-loop strategy of player i is a function of time alone, denoted by $\phi_i(t)$. If player i chooses $\phi_i(t)$, this function determines the actions that he takes at each time $t \in [0, T]$. Thus,

$$u_i(t) = \phi_i(t).$$

Choosing $\phi_i(t)$ means that player i is committed to a time path of action. For this reason, open-loop strategies are sometimes called “path strategies,” as in Ref. 3.

Let $\phi = (\phi_1, \phi_2, \dots, \phi_n)$ denote the vector of open-loop strategies chosen by the players. Given x_0 and ϕ , assume the differential equation system yields a unique solution path $x^*(t)$. The payoff of player i is then

$$W_i(x_0, \phi) = \int_0^T \exp(-r_i t) B_i(x^*(t), \phi(t), t) dt + \exp(-r_i T) S_i(x_T, T).$$

Given $\phi = (\phi_1, \phi_2, \dots, \phi_n)$, we can represent it as $(\phi_i, \bar{\phi}_{-i})$. Define an open-loop Nash equilibrium as a strategy profile $\bar{\phi}$ such that no player can gain by deviating from it, that is, for all i it holds that

$$W_i(x_0, \bar{\phi}) \geq W_i(x_0, \phi_i, \bar{\phi}_{-i}).$$

for all admissible strategies ϕ_i .

To find an open-loop Nash equilibrium, the usual method is to employ the Maximum Principle to derive the necessary conditions for the optimal time path of action of each player, given the open-loop strategies of other players. Sufficiency conditions must also be verified. Finally, one searches for a fixed point. For relatively simple games, an open-loop Nash equilibrium can be found analytically. In other situations, one must rely on numerical methods [4,5].

Example 1. Competition under sticky price using open-loop strategies. Consider a game between two firms

producing a homogeneous good. Let $u_i(t)$ denote the output of firm i at time t . Its production cost is $C(u_i) = cu_i - \frac{1}{2}(u_i)^2$. The total supply is $S(t) = u_1(t) + u_2(t)$. Given the price $p(t)$ the market demand is $D(t) = a - p(t)$. The price is sticky and does not adjust instantaneously to equate demand with supply. Assume that the rate of change of the price is proportional to the excess demand:

$$\frac{dp}{dt} = \theta(a - p(t) - u_1(t) - u_2(t)).$$

The parameter $\theta > 0$ is the speed of adjustment.

Each firm takes the above law of price adjustments as given, and seeks to maximize the integral of its stream of discounted profit.

Assume that firms use open-loop strategies. Each firm i chooses a time path of its output $u_i(t)$, taking as given the time path of its rival's output. Let $r > 0$ be the rate of discount, common to both firms. Firm i solves the following optimal control problem:

$$J_i = \max \int_0^\infty \exp(-rt) (p(t)u_i(t) - C(u_i(t))) dt.$$

subject to

$$\begin{aligned} \frac{dp}{dt} &= \theta(a - p(t) - u_i(t) - \phi_j(t)), \\ \text{where } p(0) &= p_0 \text{ (given).} \end{aligned}$$

One sets up the Hamiltonian function for firm i , with λ_i as the current-value costate variable:

$$\begin{aligned} H_i &= \exp(-rt) \left[pu_i(t) - cu_i(t) - \frac{1}{2}(u_i(t))^2 \right] \\ &+ \exp(-rt) \lambda_i(t) \theta [a - p(t) - u_i(t) - \phi_j(t)]. \end{aligned}$$

The necessary conditions are

$$\begin{aligned} p - c - u_i - \lambda_i u_i &= 0 \\ \frac{d\lambda_i}{dt} &= r\lambda_i - u_i + \theta\lambda_i \\ \frac{dp}{dt} &= \theta[a - p - u_i - \phi_j]. \end{aligned}$$

The transversality condition is

$$\lim_{t \rightarrow \infty} \exp(-rt) \lambda_i(t) = 0.$$

Since the two firms are identical, consider a symmetric open-loop Nash equilibrium, where $u_i = u_j = u$. Solving the above equations, one obtains the open-loop strategies. It can be shown that along the equilibrium path, the state variable converges to the steady-state value

$$p_{\infty}^{OL} = \frac{a(2\theta + r) + 2c(\theta + r)}{3r + 4\theta}.$$

Notice that if $r \rightarrow 0$ or $\theta \rightarrow \infty$ the steady-state value will be the same as the static Cournot equilibrium price, $p^C = \frac{a+c}{2}$.

Interestingly, in the opposite case where $r \rightarrow \infty$ or $\theta \rightarrow 0$, the steady-state value will be the same as the perfect competition price, where each firm's output equates its marginal cost to the price.

A nice property of open-loop equilibria is that they satisfy a property called *time-consistency*. This means that given an open-loop Nash equilibrium strategy profile $\bar{\phi}$, if at any point of time $s \in (0, T)$ player i reconsiders the game and wants to maximize his payoff starting from time s , he would find that the solution is to use the same strategy, given that all other players have not deviated from their equilibrium strategies. The time-consistency property follows from the fact that Bellman's Principle of Optimality applies to each player's optimization problem.

On the other hand, if by mistake some players have deviated from his planned course of action (or perhaps if there is some unexpected shock in the system) so that the stock size x_s is different from what was anticipated at time zero, then at s the players will in general find that they would be better off by switching to another strategy. We conclude that open-loop Nash equilibria are not robust to "trembling-hand" deviations. One may say that open-loop Nash equilibria are not "subgame perfect." For this reason, many researchers prefer a different equilibrium concept, called *Markov-perfect Nash equilibrium*. Before explaining this concept, we must define the concept of Markovian strategies (sometimes called *closed-loop strategies*).

MARKOVIAN STRATEGIES, MARKOVIAN NASH EQUILIBRIUM, AND MARKOV-PERFECT NASH EQUILIBRIUM

A Markovian strategy of player i is a function ψ_i that determines at any (state, time) pair (x, t) the action that he takes at t :

$$u_i(t) = \psi_i(x(t), t).$$

Markovian strategies are sometimes called *decision-rule strategies* (or *closed-loop strategies*) since under Markovian strategies, the action of player i at time t is conditioned on the currently observed value of the vector of state variables x . In the degenerate case where a Markovian strategy is insensitive to x , that is, it does not contain x as an argument, then it is an open-loop strategy.

Given a profile of Markovian strategies, one for each player, $\psi = (\psi_1, \psi_2, \dots, \psi_n)$ the system of differential equations is

$$\frac{dx}{dt} = f(x(t), \psi(x(t), t))$$

with initial condition $x(0) = x_0$.

Assume that this system has a unique solution, denoted by $x^{**}(t)$. The payoff of player i is

$$J_i(x_0, \psi) = \int_0^{\infty} \exp(-r_i t) B_i(x^{**}(t), \psi(x^{**}(t), t), t) dt + \exp(-r_i T) S_i(x_T^{**}, T).$$

Define a Markovian Nash equilibrium as a strategy profile $\bar{\psi}$ such that no player can gain by deviating from it, that is, for all $i \in N$, it holds that

$$J_i(x_0, \bar{\psi}) \geq J_i(x_0, \psi_i, \bar{\psi}_{-i}),$$

for all admissible strategies ψ_i . Note that this inequality is required to hold only for a given $x(0) = x_0$, the initial condition at time zero. Markovian Nash equilibrium are sometimes called *decision-rule Nash equilibrium*.

Markovian Nash equilibria are time-consistent, for the same reason that makes open-loop Nash equilibria time-consistent. Also, like open-loop Nash equilibria, without further restrictions Markovian Nash

equilibria are not robust to trembling-hand deviations. In other words, although the actions induced by a Markovian Nash equilibrium strategy profile are credible along the equilibrium trajectory x^{**} they are in general not credible when the system is off the equilibrium path. [A simple example is given in Ref. 1 (p. 102.)] For this reason, a stronger property is desirable: subgame perfection, a concept attributed to Selten [6]. A Markovian Nash equilibrium that satisfies the subgame-perfect property is called a *Markov-perfect Nash equilibrium*.

To introduce the idea of subgame perfection in continuous-time, consider any arbitrary (state, date) pair (x, t) , and the system of differential equations

$$\frac{dx(\tau)}{d\tau} = f(x, \psi(x, \tau), \tau) \text{ for } \tau \geq t \text{ and } x(t) = x.$$

Assume this equation yields a unique solution. Define the performance index for player i at the (state, date) pair by

$$V_i(x, t, \psi) = \int_t^T \exp(-r(\tau - t)) B_i(x(\tau), \psi(x(\tau), \tau), \tau) d\tau + \exp(-r(T - t)) S_i(x_T, T).$$

Define a Markov-perfect Nash equilibrium (also called a *feedback Nash equilibrium*) as a strategy profile $\bar{\psi}$ such that, at any (state, date) pair (x, t) , the following inequality holds

$$V_i(x, t, \bar{\psi}) \geq V_i(x, t, \psi_i, \bar{\psi}_{-i}),$$

for all admissible ψ_i .

It is important to stress the requirement that this inequality hold for all possible (state, date) pairs, not just for the initial pair at time zero. To be Markov-perfect, a Markovian Nash equilibrium must satisfy the property that the continuation of the given decision rules constitutes a Nash equilibrium when viewed from any future (date, state) pair. This requirement corresponds to the concept of subgame-perfect Nash equilibrium originally proposed by Selten [6] for games that take place in discrete-time.

To find a Markov-perfect Nash equilibrium, one normally makes use of the Hamilton–Jacobi–Bellman (HJB) equations. Let V_i denote the value function for player i .

The HJB equation for player i is

$$r_i V_i(x, t) - \frac{\partial V_i}{\partial t} = \max_{u_i} \left[B_i(x, u_i \cdot \psi_{-i}, t) + \frac{\partial V_i}{\partial x} f(x, u_i, \psi_{-i}, t) \right],$$

with the boundary condition $V_i(x, T) = S_i(x, T)$.

If T is infinite, the above boundary condition is replaced by

$$\lim_{t \rightarrow \infty} \exp(-r_i t) V_i(x(t), t) = 0.$$

In an important class of infinite-horizon differential games, both the objective function and the transition equation are independent of time. For such problems, called *infinite-horizon autonomous* problems, it is natural to focus on stationary strategies (i.e., strategies that specify the control variables as functions of the state variable only, independent of time). In that case, the value functions are also independent of time.

Example 2. Competition under sticky price using Markovian strategies.

Return to Example 1 above, and modify the assumption about the behavior of firms. Assume that they use decision-rule strategies, so that $u_i(t) = \psi_i(x(t), t)$. Since the problem is linear quadratic, it is natural to conjecture that the value function is quadratic in the state variable. Furthermore, since in this problem time does not enter directly in the benefit function B_i and the transition equation, one expects that the value function is independent of time. Then the HJB equation for firm i is

$$rV_i(p) = \max_{u_i} \left[pu_i - cu_i - \frac{1}{2}(u_i)^2 + \frac{dV_i}{dp} \theta(a - p - u_i - \psi_j(p)) \right].$$

Let $V_i = A_i + B_i p + D_i p^2$ where A_i, B_i , and D_i are to be determined. Focus on the linear Markovian strategies of the form $u_i(t) = \alpha_i + \beta_i p(t)$. Then it can be shown that in equilibrium the firms use the same linear Markovian strategy, with

$$\begin{aligned}
\alpha_i &= \alpha_j = \alpha = (1 - \theta K) > 0 \\
\beta_i &= \beta_j = \beta = \theta E - c < 0 \\
K &\equiv \frac{r + 6\theta - \sqrt{(r + 6\theta)^2 - 12\theta^2}}{6\theta^2} > 0 \\
E &= \frac{c - a\theta K - 2c\theta K}{r + 3\theta + 3K\theta^2}.
\end{aligned}$$

(Here the positive root K is chosen to ensure convergence of p to a steady-state).

Notice that $\alpha > 0$, indicating that the equilibrium decision-rule strategies instruct firms to produce more if they observe a higher price. This suggests that firms are more competitive in the Markov-perfect Nash equilibrium than in the open-loop Nash equilibrium. To verify this, compute the steady-state price under the Markov-perfect Nash equilibrium,

$$p_\infty^M = \frac{a + 2c - 2\theta E}{3 - 3\theta K}.$$

In the limiting case, where $r \rightarrow 0$ or $\theta \rightarrow \infty$, one can see that the Markov-perfect steady-state price is lower than the steady-state price under open-loop Nash equilibrium. The reason is that if each firm expects its rival to produce more when the price is higher, then it has little incentive to restrict its output to raise the price.

It is worth noting that open-loop Nash equilibrium and Markov-perfect Nash equilibrium can be thought of as based on two alternative assumptions about the ability of players to precommit. In an open-loop Nash equilibrium, players commit to a whole time path of actions. In a Markov-perfect Nash equilibrium, players cannot precommit at all. One can argue that in some cases, players may be able to commit to actions in the near futures (e.g., by forward contracts), but not to actions in the distant future [3]. Think of a continuous-time model where a game begins at time 0 and ends at a fixed time T , and there are k periods of equal length δ , where $k\delta = T$. At the beginning of each period, agents can commit to a path of action during that period. The special case where $k = 1$ corresponds to the open-loop formulation, and open-loop Nash equilibrium is the appropriate equilibrium concept. At the

other extreme, where $\delta \rightarrow \infty$ the appropriate equilibrium concept is Markov-perfect Nash equilibrium.

The choice of equilibrium concepts is to some extent dependent on tractability. The relative ease of finding an open-loop Nash equilibrium is one of its attractive features.

STACKELBERG EQUILIBRIUM

There are dynamic-game situations where players do not make their moves simultaneously. Consider a two-player game where Player 1 has priority of moves over Player 2. We call Player 1 the leader and Player 2 the follower. The leader is sometimes called the *Stackelberg leader*, a term borrowed from economics, and the equilibrium concept is called the *Stackelberg equilibrium*.

There are several distinct notions of Stackelberg equilibrium, depending on what strategies are admitted and on the exact nature of the priority of moves.

Open-Loop Stackelberg Equilibrium

When Player 1 can announce at the start of the dynamic game the whole sequence of her moves and is able to commit to it, we say she is the “open-loop Stackelberg leader.” Player 2 takes the time path of action chosen by the leader as given, and chooses his own time path of action in response to maximize his payoff. The open-loop strategy chosen this way by the follower is called his “reaction” to the leader’s path strategy. The leader knows the follower’s reaction to each of her possible time paths. She then chooses her best time path, that is, the one that maximizes her payoff, taking into account the response of the follower.

Technically, a common method of finding the open-loop Stackelberg equilibrium is to treat the follower’s necessary conditions as constraints that the leader faces in formulating her optimization problem. Consider a game where x is the state variable (a scalar) and u_1 and u_2 are the control variables of the leader and the follower respectively. Let λ denote the follower’s costate variable, and express u_2 as a function of λ and x . The equation of motion of the costate variable λ in

the follower's necessary conditions is an additional differential equation that the leader faces. She must therefore treat this costate variable, λ , as a second state variable. The leader then solves an optimal control problem involving two state variables, x and λ . Let μ and γ be her costate variables associated with these state variables. An interesting feature of the leader's optimization problem is that while x_0 is given, λ_0 is not. In general, the whole time path of λ depends on the leader's time path u_1 (which is known to the follower at the start of the game). Therefore λ_0 generically depends on the time path u_1 . When this is the case, we say that λ_0 is controllable [1, Chapter 5]. When λ_0 is controllable, the leader will want to influence it so as to maximize her payoff. This means that her optimal choice of λ_0 , denoted by λ_0^* , must be such that any small deviation of λ_0 from λ_0^* would not improve her payoff. This implies that the leader's initial shadow price $\gamma(0)$ must be zero. Therefore $\gamma(0) = 0$ is a necessary condition for the leader, if λ_0 is controllable.

An undesirable property of open-loop Stackelberg equilibrium is that it is generally time-inconsistent. To see this, recall that $\gamma(0) = 0$ is a necessary condition for the leader. Typically, $\gamma(t)$ is not identically zero for all $t > 0$. Consider some time t_1 such that $\gamma(t_1)$ is different from zero. If at time t_1 the leader is allowed to revise her path strategy, the necessary conditions of her optimization problem at t_1 would imply that she would want the new $\gamma(t_1)$ to be zero. Resetting $\gamma(t_1)$ from a nonzero value to zero implies resetting the whole time path of her control variable $u_1(t)$ for $t \geq t_1$. This establishes the time-inconsistency of open-loop Stackelberg equilibrium.

The time-inconsistency of the leader's initial plan would be known by any smart follower. It follows that the leader's plan is not credible. For this reason, alternative concepts of Stackelberg equilibrium must be found.

Stagewise Stackelberg Equilibrium

We define a stagewise Stackelberg leader is a leader that cannot credibly announce a whole time path of her action. Instead, it is assumed that at each date t , she chooses $u_1(t)$ before

Player 2 chooses his move. Thus the leader only leads at each stage (date), but does not have the overall leadership.

To solve for a stagewise Stackelberg equilibrium, dynamic programming can be used. The solution method is most easily understood in a setting with discrete-time and a finite horizon. In the last period, a static Stackelberg equilibrium is found. The payoff of each player for the last period can be computed as a function of the opening stock of the last period. Working backwards, the equilibrium strategies for the second-last period can be found, and so on.

In continuous-time, the solution method for a stagewise Stackelberg equilibrium is via the use of the HJB equations, which are not solved simultaneously as in the case of the Markov-perfect Nash equilibrium. Instead, the HJB equation for the follower is considered first, to express the control variable of the follower as a function of the leader's control variable and the parameters of the follower's value function. Such a "reaction function" is then fed into the leader's HJB equation, and the necessary conditions for the leader's optimal control are obtained. These are then used to solve for the parameters of the follower's value function [7].

Stagewise Stackelberg equilibria are time-consistent because this equilibrium concept is based on Bellman's Principle of Optimality.

Global Stackelberg Equilibrium with Decision-Rule Strategies

An alternative equilibrium concept for leader-follower games is global Stackelberg leadership, where the leader uses a decision rule that determines her control variable as a function of the state variable. The set of decision rules from which the leader chooses her strategy is normally restricted, for example, her control variable must be a linear affine function of the state variable, where the two parameters are to be chosen optimally.

Example 3. Taxing a polluting monopolist. In this game, the leader is a government that wants to maximize social welfare and the follower is a monopolist that produces an

output which emits pollution as a by-product. The state variable is the stock of pollution, denoted by $X(t)$. The control variable of the follower is the output, $y(t)$, which is equal to the emission rate. The pollution stock evolves according to the differential equation

$$\frac{dX}{dt} = y - \delta X.$$

Here $\delta > 0$ is the rate of decay of the pollution stock. Consumers suffer damages caused by the pollution stock. Their aggregate damage cost is $\frac{\sigma}{2}X^2$, where σ is a positive parameter.

The government's control variable is the tax rate $\theta(t)$ per unit of output. The government's choice of the tax is restricted to a family of linear affine function $\theta(t) = \alpha X(t) + \beta$, where α and β are to be chosen optimally.

Assume production cost is c per unit. The demand curve is given by $p = A - By$ where p is the price, and A and B are positive constants. The profit of the monopolist is $\pi(t) = [p(t) - c - \theta(t)]y(t)$. The monopolist chooses the time path of output to maximize

$$\int_0^\infty \exp(-\rho t)[(A - c)y - By^2 - (\alpha X + \beta)y]dt$$

subject to $\frac{dX}{dt} = y - \delta X$.

Assume $A - c > \beta$ and $\alpha > 0$. The monopolist's optimal control problem has a unique solution. The pollution stock converges to a steady-state

$$X_\infty(\alpha, \beta) = \frac{(A - c - \beta)(\rho + \delta)}{\alpha\rho + 2\alpha\delta + 2\delta B(\rho + \delta)}.$$

The time path of the pollution stock is

$$X(t) = (X_0 - X_\infty)\exp(\mu(\alpha)t) + X_\infty,$$

where

$$\mu(\alpha) \equiv \frac{1}{2}(\rho - \sqrt{\Delta}) < 0$$

and

$$\Delta \equiv (\rho + 2\delta)^2 + \frac{2\alpha(\rho + 2\delta)}{B}.$$

The monopolist's output can be expressed in the feedback form

$$y(X, \alpha, \beta) = \delta X_\infty(\alpha, \beta) + [X - X_\infty(\alpha, \beta)][\delta + \mu(\alpha)].$$

The government's objective is to maximize the integral of discounted welfare $w(t)$ defined as the sum of consumer surplus net of pollution damage costs, producer surplus, and tax revenue

$$w = U(y) - p(y)y - \frac{\sigma}{2}X^2 + \pi + \theta y,$$

where $U(y) \equiv \int_0^y p(y)dy$. After simplification, the government's objective function becomes

$$\max \int_0^\infty \exp(-\rho t)[U(y) - cy - (\sigma/2)X^2]dt.$$

The government chooses the parameters α and β to maximize this objective function, knowing that $y = y(X, \alpha, \beta)$. The solution is

$$\alpha^* = \frac{2\sigma}{\rho + 2\delta} \quad \text{and} \\ \beta^* = \frac{[\sigma - B(\rho + \delta)\delta - (\rho + 2\delta)\alpha^*]X_\infty}{\rho + \delta},$$

where

$$X_\infty = \frac{(A - c)(\rho + \delta)}{\sigma + B\delta(\rho + \delta)}.$$

It can be verified that this solution yields a time path of pollution that is identical to what a benevolent dictator who can directly control y would choose. Therefore the linear tax rule found above achieves the first-best outcome. It follows that the commitment to such a tax rule is credible.

EXTENSIONS OF DIFFERENTIAL GAMES

Non-Markovian Strategies

Markovian strategies are restrictive: players cannot condition their actions on the full history of the game. Non-Markovian strategies allow players to make threats which can help enforce cooperation. A powerful type of non-Markovian strategies is called *trigger strategy*: a player can threaten to switch from a cooperative mode to a punishment mode if

he observes that other players have deviated from a cooperative mode. It is assumed that if a player defects at time t , other players will start to punish him at time $t + \varepsilon$, where ε is a fixed positive time delay. As shown in Ref. 1, if the time delay is small enough and the rate of discount is not too high, trigger strategies can ensure full cooperation.

Stochastic Differential Games

Uncertainty can be incorporated into differential games. Two common ways of modeling uncertainty are (i) allowing a small random disturbance in the evolution of the state variables, often represented by a Wiener process, and (ii) introducing piecewise deterministic processes, where uncertain changes in the environment occur at unknown isolated points of time. Both modeling strategies are discussed in Ref. 1.

DIRECT SEARCH METHODS

ROBERT MICHAEL LEWIS

College of William & Mary,
Williamsburg, Virginia

INTRODUCTION

Direct search methods were first formally proposed in the late 1950s and early 1960s [1–3]. They have remained popular with users due to their simplicity and their practical success on a variety of problems. Well-known examples of some of the original direct search methods include the simplex method of Nelder and Mead [4] (not to be confused with the simplex algorithm of linear programming) and the pattern search method of Hooke and Jeeves [2].

It is difficult to give a succinct, precise characterization of direct search methods. The term *direct search* was introduced by Hooke and Jeeves in 1961 [2] in connection with their algorithm for unconstrained optimization:

We use the phrase “direct search” to describe sequential examination of trial solutions involving comparison of each trial solution with the “best” obtained up to that time together with a strategy for determining (as a function of earlier results) what the next trial solution will be. The phrase implies our preference, based on experience, for straightforward search strategies which employ no techniques of classical analysis except where there is a demonstrable advantage in doing so.

From this perspective, direct search involves the comparison of each trial solution with the best previous solution. The stated preference

for “straightforward search strategies which employ no techniques of classical analysis” means that direct search methods do not rely on models or approximations, such as the linear (first-order) model used by steepest descent or the quadratic (second-order) model used by Newton’s method. Instead, direct search methods work *only* with values of the objective computed at various trial points, and for this reason are sometimes called *zeroth-order methods* since no derivatives are involved. Nevertheless, many direct search strategies share important mathematical features with derivative-based techniques such as steepest descent. In particular, a properly designed direct search method will enjoy analytical guarantees similar to those found for steepest descent [e.g., convergence to a Karush–Kuhn–Tucker (KKT) point], even without explicit use of the gradient [5,6].

Direct search methods are most easily understood for the case of unconstrained minimization,

$$\text{minimize } f(x), \quad (1)$$

where the objective $f : \mathbb{R}^n \rightarrow \mathbb{R}$. The discussions in sections titled “Compass Search for Unconstrained Minimization”, “Characteristics of Direct Search Methods”, and “Direct Search Methods for Unconstrained Minimization” focus on this case. Direct search techniques for problems with bound, linear, and nonlinear constraints are discussed in the section titled “Direct Search Methods for More General Optimization”.

COMPASS SEARCH FOR UNCONSTRAINED MINIMIZATION

The basic ideas underlying direct search methods are easily illustrated with *compass search*. Compass search is an exceedingly simple instance of a direct search method, yet one for which there are surprisingly

Figure 1. A version of compass search applied to the Broyden tridiagonal function.

strong convergence guarantees.

At the beginning of iteration k of compass search one has a current estimate x_k of the solution of Problem (1) and a parameter Δ_k that determines the length of trial steps. Let $e_1, e_2, \dots, e_n$ denote the standard unit basis vectors for $\mathbb{R}^n$. Compass search then proceeds with a local search around x_k , trying steps of the form $x_k \pm \Delta_k e_i$, $i = 1, \dots, n$, looking for a point that improves the objective. Any such point may be taken as the next iterate x_{k+1} . If no such point is found—and only if no such point is found—the step-length parameter is decreased ($\Delta_{k+1} = \Delta_k/2$ is typical). Note that the search is not required to find a trial point that has the lowest objective value—any trial point that improves on x_k will suffice. The name *compass search* is derived from the two-dimensional situation,

where the trial steps correspond to the cardinal points of the compass (east, west, north, and south). An example of several iterations of compass search applied to the Broyden tridiagonal function [7] is shown in Figure 1, with level curves of the objective shown in the background and the minimizer x_* indicated with a star. The current iterate x_k is indicated with a circle, while the trial points $x_k \pm \Delta_k e_i$, $i = 1, \dots, n$, are shown as squares. For $k > 0$, the configuration from the previous iteration is also included in the background.

An iteration at which Δ_k is reduced is called *unsuccessful*. For k in the subsequence of such iterations, under mild assumptions on the objective, one can show that $\|\nabla f(x_k)\| = O(\Delta_k)$. The argument for this relation is given in the section titled “Generating Set Search” as part of the

discussion of generating set search (GSS) methods for unconstrained minimization since compass search is one instance of a GSS method. In practice, the algorithm is terminated once Δ_k falls below a predetermined threshold, which is justified by the relation $\|\nabla f(x_k)\| = O(\Delta_k)$ at unsuccessful iterations.

CHARACTERISTICS OF DIRECT SEARCH METHODS

Because direct search methods neither compute nor approximate derivatives, they are often described as being “derivative-free.” This description is incomplete, however, since the same can be said of other methods that are very different in nature, such as genetic algorithms.

One distinctive feature of direct search methods in the case of unconstrained optimization is that they do not require numerical function values: the relative rank of objective values is sufficient [1,8]. This makes direct search useful in situations that involve subjective judgments of “better” and “worse,” for instance, the optimization of the perceived quality of sound by systematically varying the settings of a hearing aid [9]. Other distinctive characteristics of direct search methods can be made clearer by contrasting them with other nonlinear optimization methods.

Relation to Methods based on Taylor’s Series

Direct search methods do not rely in an intrinsic way on the construction of models of the objective in Problem (1). Many classical approaches, on the other hand, are explicitly based on the use of a Taylor’s series approximation of the objective as a model of the objective. Steepest descent uses first derivatives and the first-order Taylor polynomials to construct local linear approximations of f , while Newton’s method uses first and second derivatives and the second-order Taylor polynomial to construct local quadratic approximations of f . Quasi-Newton methods use quadratic approximations of the objective in which the Hessian is approximated via secant updates using the first derivative.

Intermediate to methods based on Taylor series and direct search are the methods of Mifflin and May, and more recent approaches that have appeared under the name of *implicit filtering* [10,11]. In Mifflin’s method for unconstrained optimization [12] and May’s method for linearly constrained optimization [13], a finite-difference interval is chosen and Newton’s method is applied with derivatives computed using this interval until no further progress is found. The finite-difference interval is then decreased and the process repeated.

Relation to Other Derivative-Free Methods

There exist other algorithms that are classified as derivative-free but which nonetheless rely on models of the objective function. These models are typically low-order polynomials constructed from values of the objective via regression or interpolation, though models based on radial basis functions [14–17] or kriging [18,19] also have been proposed.

An early example of such a method is that of Powell [20,21], which constructs a quadratic model of the objective along each search direction so that when the method is applied to a convex quadratic, it produces a sequence of conjugate search directions. Glad and Goldstein proposed an algorithm that constructs local quadratic models of the objective via linear least-squares regression [22]. Their approach was motivated by objectives whose values can only be obtained with errors that are large enough to make the use of finite-difference approximation of derivatives for a Taylor series model problematic.

More recently, other model-based derivative-free approaches have appeared under the name of *derivative-free optimization* (DFO). DFO algorithms also construct local quadratic models via interpolation but use incompletely determined quadratic models to reduce computational cost [23–27]. Much of the work on DFO methods that construct models via sampling has focused on the question of the interaction between the quality of the model (particularly with respect to second-order information) and the geometric properties (*poisedness*) of the sample points used to construct the model.

Powell [25] initially proposed using a simplex because a simplex contains the minimum number of points $(n + 1)$ required to capture first-order effects, and thus avoid the often prohibitive cost associated with requiring $O(n^2)$ sample points to build a full quadratic model at each iteration of the search. As the search proceeds, the simplex is monitored to ensure that it does not collapse into a lower-dimensional hyperplane. Powell's more recent work allows users to choose the number of sample points to be used to construct the model for each iteration, ranging from $\min\{2n + 1, n + 6\}$ to $(n + 1)(n + 2)/2$, with care taken to ensure the distribution of the points used to build the model of the objective [28–30]. There are no analytical results guaranteeing first-order convergence. Another approach is to attempt to capture full second-order effects using $O(n^2)$ sample points, starting with a minimal linear model at the first iteration and building up to a full quadratic model as more and more sample points are accumulated during the course of the search [23]. For this approach there exist first-order convergence results in the unconstrained case [31].

Response surface methodology (RSM) is another approach based on polynomial modeling. RSM was originally proposed by Box and Wilson [32] as a way to optimize a mean response function whose measured values contain random errors. Because derivatives of the response function are not available, samples of the response function are taken at designated points in a neighborhood of the current iterate and a local linear or quadratic model of the mean response is constructed via multiple linear regression. (The simplicity of working directly with the results of the sampling, rather than constructing an approximation, led Box to propose the evolutionary optimization (EVOP) direct search method [1] as an alternative for finding optima experimentally.)

In RSM, the objective is stochastic and models are constructed using regression, while in DFO, the objective is deterministic and models are typically constructed via interpolation. DFO and RSM share a common concern with experimental design; monitoring the geometry of the set of sample

points during the course of such algorithms is critical.

DIRECT SEARCH METHODS FOR UNCONSTRAINED MINIMIZATION

Direct search methods for unconstrained optimization can be grouped into two broad categories: *generating set search* and *simplex methods* (again, *not* to be confused with the simplex method for linear programming). The principles behind each of these classes of methods make it a relatively straightforward matter to devise new algorithms and explain the wealth of variations that have appeared over the years.

Generating Set Search

GSS methods [5] include the simple compass search algorithm described previously, the original pattern search method of Hooke and Jeeves [2], methods with adaptive sets of search directions such as Rosenbrock's method [33], and later methods such as parallel multidirectional search [34–36] and generalized pattern search algorithms [6].

GSS methods include, at every iteration, a set of potential search directions that form a positive spanning set for $\mathbb{R}^n$, a feature that makes it possible to prove convergence results for GSS methods that are analogous to similar results for steepest descent. A positive spanning set for $\mathbb{R}^n$ is a set of vectors $\{v_1, v_2, \dots, v_r\}$ such that

$$\begin{aligned} \{v \in \mathbb{R}^n \mid v = \alpha_1 v_1 + \dots + \alpha_r v_r, \alpha_i \\ \geq 0, i = 1, \dots, r\} = \mathbb{R}^n. \end{aligned}$$

A positive spanning set is a set of generators for $\mathbb{R}^n$ viewed as a cone, hence the name *generating set search*. In the case of compass search, the positive spanning set is $\{\pm e_i \mid i = 1, \dots, n\}$, which is a positive basis. A positive basis is a minimal positive spanning set; a positive basis for $\mathbb{R}^n$ can have as few as $n + 1$ or as many as $2n$ elements [37].

An elaboration of compass search is *coordinate search*. A single iteration of coordinate search is described in Algorithm 1. Here, the set of potential search directions

is exponential in size since it consists of the vectors representing all possible combinations of 1, 0, and -1 except the zero vector. This set clearly is a positive spanning set since it includes the set $\{\pm e_i | i = 1, \dots, n\}$, which is a positive basis. But the search does not consider all trial

points defined by the positive spanning set. Rather, it dynamically selects between n and $2n$ trial steps from those defined by the positive spanning set and, in fact, in the worst case (i.e., no improvement on the current iterate x_k), it considers exactly the same set of trial points as compass search.

Algorithm 1. An iteration of coordinate search for unconstrained minimization.

Step 0. Let $x_+ = x_k$.
Step 1. for $i = 1, \dots, n$
 if $(f(x_+ + \Delta_k e_i) < f(x_+))$
 $x_+ = x_+ + \Delta_k e_i$
 else if $(f(x_+ - \Delta_k e_i) < f(x_+))$
 $x_+ = x_+ - \Delta_k e_i$
 end
 end
Step 2. if $x_+ = x_k$ then set $\Delta_{k+1} = \Delta_k/2$ and $x_{k+1} = x_k$; otherwise, set $\Delta_{k+1} = \Delta_k$
 and $x_{k+1} = x_+$.

The pattern search method of Hooke and Jeeves adds speculative *exploratory moves* in an attempt to accelerate coordinate search. To illustrate the exploratory moves, suppose that iteration $k - 1$ was successful, so that $x_k \neq x_{k-1}$. In this case, the following heuristic is applied: since the move from x_{k-1} to x_k produced a decrease in f , immediately try another step, of the same length and along the same direction, from x_k . Such a step is called a *pattern step*, denoted by x_p . Then, regardless of whether $f(x_p) < f(x_k)$, the algorithm proceeds to one iteration of coordinate search around x_p . If none of the exploratory moves leads to an improvement in the objective, the search falls back to an iteration of coordinate search around x_k . Again, the positive spanning set is exponential in size, but the search dynamically selects between $n + 1$ and $4n + 1$ trial points. In the worst case (i.e., no improvement on the current iterate x_k) it, too, ultimately considers the same set of trial steps as compass search.

In addition to including a positive basis for $\mathbb{R}^n$ in the set of search directions, GSS methods feature a step-length control parameter Δ_k that determines the length of steps at each iteration. A crucial feature of GSS methods is that one is not allowed to *decrease* the step-length control parameter until one has determined that no improvement can be found

among the steps along *any* of the directions in a positive basis (which need not be unique) contained in the set of search directions. Such an iteration is called *unsuccessful*. At unsuccessful iterations, under mild assumptions on f , one can show that $\|\nabla f(x_k)\| = O(\Delta_k)$. This is a consequence of the fact that if x_k is not a stationary point, then at least one vector in a positive basis must be within 90° of the direction of steepest descent and thus must be a descent direction—even though the gradient of f at x_k is unknown. For GSS methods one can also show that there will be an infinite number of unsuccessful iterations and so $\Delta_k \rightarrow 0$ as $k \rightarrow \infty$. As a consequence, under standard assumptions one obtains $\lim_{k \rightarrow \infty} \|\nabla f(x_k)\| = 0$, a stationarity result similar to that for steepest descent. This means that a subsequence of the iterates will converge to a stationary point [5,6]. Moreover, as with steepest descent, one can prove local convergence results: under standard assumptions of second-order sufficiency (local convexity) at a local minimizer x_* , once the sequence of iterates is sufficiently close to x_* the entire sequence is guaranteed to converge to x_* [38]. It is even possible to make statements about the Hessian of the objective at limit points for GSS methods that are stronger than what can be said in the case of steepest descent [39].

Adaptive direction methods attempt to accelerate the search by constructing directions designed to use information about the curvature of the objective obtained during the course of the search. For example, Rosenbrock's method [33] was consciously derived to cope with the peculiar features of Rosenbrock's famous "banana function," the minimizer of which lies inside a narrow, curved valley (see Ref. 3, Figure 3.4). As the algorithm progresses, an orthogonal set of search directions is rotated in order to orient one of the directions in a promising direction of improvement. More general ideas for adaptive direction methods to acquire and use information about the structure of the objective, curvature in particular, have appeared in recent years [40–46].

Simplex Methods

The simplex-based direct search methods try steps along a heuristic direction of steepest descent. Two well-known examples of such algorithms are that of Spendley *et al.* [47] and that of Nelder and Mead [4].

Spendley, Hext, and Himsworth observed that a simplex ($n + 1$ points in $\mathbb{R}^n$ not lying in a proper subspace of $\mathbb{R}^n$) is the minimal number of points sufficient to capture first-order information about the objective (that is, to construct a linear model). In their algorithm, at any iteration there is a set of $n + 1$ points forming a simplex at which the objective values are known. Let $v_0, v_1, \dots, v_n$ be the vertices of the simplex, ordered from best to worst in the sense that $f(v_0) \leq f(v_1) \leq \dots \leq f(v_n)$. A trial point is computed by reflecting the vertex v_n with the highest objective value through the centroid $c = (v_0 + \dots + v_{n-1})/n$

of the opposite face of the simplex. Figure 2a illustrates this reflection. The new simplex that results is accepted if the reflected vertex $v_r = v_n + 2(c - v_n)$ yields a lower value of f than the vertex v_{n-1} with the second highest function value in the original simplex. This acceptance criterion is motivated by the observation that if v_r becomes v_n at the next iteration (i.e., it has the highest function value in the new simplex), the new reflection step will be the former worst vertex.

The Nelder–Mead simplex algorithm is a variation on this basic idea that introduces a simple line search of the form $v_n + \alpha(c - v_n)$, with four possible choices for α . Typical choices are $\alpha \in \{\frac{1}{2}, \frac{3}{2}, 2, 3\}$, as illustrated in Figure 2b. The line search allows the shape of the simplex to deform (for any choice of α other than 2), which is intended to allow the simplex to adapt to the local behavior of the objective.

There is long-standing numerical evidence that algorithms such as the Nelder–Mead simplex algorithm can stall away from stationary points of the objective. Moreover, McKinnon [48] constructed a family of functions in $\mathbb{R}^2$ which demonstrate analytically that the Nelder–Mead simplex algorithm can fail to converge to a stationary point of f . In these examples, repeated deformations cause the simplices to collapse (i.e., some of the interior angles tend to zero) and converge to a straight line that is orthogonal to the direction of steepest descent. The collapse of the simplices means that the search is reduced to a line that does not contain a minimizer.

Interestingly, these examples are very delicate and McKinnon found that floating-point rounding error was enough to prevent the

Figure 2. Examples of (a) the single possible trial step for the simplex algorithm of Spendley–Hext–Himsworth, and (b) the four basic trial steps for the Nelder–Mead simplex algorithm.

algorithm from converging to the nonstationary point in these examples. Experimental evidence [35] suggests that simplex algorithms fail in practice because the search direction becomes increasingly orthogonal to the direction of steepest descent. Numerous modifications to the Nelder–Mead simplex algorithm have been proposed [49–53], but many users find that the easiest response when the algorithm stalls is simply to restart with a new simplex.

Finally, the distinction between GSS methods and simplex methods is not sharp. There exist methods that are based on a simplex heuristic for generating promising search directions but which possess the feature of GSS methods of a set of search directions that positively span $\mathbb{R}^n$ [8,35,36].

DIRECT SEARCH METHODS FOR MORE GENERAL OPTIMIZATION

Direct search methods can be applied, with varying degrees of success, to constrained and nonsmooth (Lipschitz) optimization.

Bound Constraints

Direct search can be effective for bound constrained minimization:

$$\begin{aligned} & \text{minimize } f(x) \\ & \text{subject to } x \in \Omega = \{x \in \mathbb{R}^n \mid \ell \leq x \leq u\}. \end{aligned} \quad (2)$$

The simplicity of the geometry of the feasible region makes it relatively straightforward to develop specialized direct search methods for bound constrained optimization.

For instance, a simple modification of compass search results in an algorithm that, under standard assumptions, guarantees global convergence to a KKT point of Problem (2) [54]. All that is required is that attention be restricted to trial points that are feasible, that is, trial points in the set $\{x_t \in \Omega \mid x_t = x_k \pm \Delta_k e_i, i = 1, \dots, n\}$.

GSS methods can be adapted to bound constrained minimization, as in the preceding variant of compass search, by including the directions $\{\pm e_i \mid i = 1, \dots, n\}$ as search directions when near the boundary [54,55]. If x

is feasible, let $N(x, \varepsilon)$ be the cone determined by the outward-pointing normals to the constraints that are active within distance ε of x . The polar cone $T(x, \varepsilon) = N^\circ(x, \varepsilon)$ then approximates the feasible region in a neighborhood of x . The set of search directions $\{\pm e_i \mid i = 1, \dots, n\}$ always contains a set of generators for the cone $T(x, \varepsilon)$, once again illustrating the motivation for the name *generating set search*.

GSS methods are not allowed to decrease the step-length parameter Δ_k unless all feasible steps have been tried along all of the directions $\{\pm e_i \mid i = 1, \dots, n\}$ and no improvement in the objective has been found. If P_Ω represents projection onto the feasible region Ω , then under standard assumptions one can show that at unsuccessful steps (those where Δ_k is reduced), $\|P_\Omega(x_k - \nabla f(x_k)) - x_k\| = O(\Delta_k)$. One also has $\Delta_k \rightarrow 0$ as $k \rightarrow \infty$, so $\lim_{k \rightarrow \infty} \|P_\Omega(x_k - \nabla f(x_k)) - x_k\| = 0$. This means that a subsequence of the iterates will converge to a KKT point.

The search directions $\{\pm e_i \mid i = 1, \dots, n\}$ are only needed near the boundary. In the interior of the feasible region one has greater flexibility in the choice of search directions since feasibility with respect to the bound constraints is not an immediate issue. For instance, Keefer’s Simpat algorithm [56] uses the Nelder–Mead simplex algorithm in the interior of the feasible region and the Hooke and Jeeves pattern search algorithm near the boundary.

Simplex-based direct search methods are more problematic for bound constrained optimization since it is difficult to ensure that they search along directions that take into account the proximity of the boundary. In addition, mechanisms to ensure only feasible steps can cause the simplices to collapse into a lower-dimensional subspace near the boundary.

Linear Constraints

GSS methods have also been developed for general linearly constrained minimization:

$$\begin{aligned} & \text{minimize } f(x) \\ & \text{subject to } x \in \Psi = \{x \in \mathbb{R}^n \mid Ax \leq b\}. \end{aligned} \quad (3)$$

As with bound constraints, the key is to include search directions that capture the geometry of the feasible region near the current iterate. If x is feasible, let $N(x, \varepsilon)$ be the cone determined by the outward-pointing normals to the constraints that are active within distance ε of x . The polar cone $T(x, \varepsilon) = N^\circ(x, \varepsilon)$ approximates the feasible region in a neighborhood of x . In a GSS method for linearly constrained minimization the set of search directions must always contain a set of generators for the cone $T(x, \varepsilon)$. If $T(x, \varepsilon)$ has a degenerate vertex at the origin (in the sense of linear programming) the calculation of a full set of generators for $T(x, \varepsilon)$ can be an expensive polyhedral geometry calculation [57]. On the other hand, if $T(x, \varepsilon)$ does not have a degenerate vertex at the origin, a straightforward linear algebra calculation yields the generators [57, 58].

As with GSS methods for bound constrained minimization, the algorithm is not allowed to decrease the step-length parameter unless all feasible steps have been tried along at least a minimal set of generators for $T(x, \varepsilon)$ and no improvement in the objective has been found. Again, under mild assumptions, one can show that a suitable measure of stationarity that is zero at KKT points is $O(\Delta_k)$ at unsuccessful iterations. One also has $\Delta_k \rightarrow 0$ as $k \rightarrow \infty$ and so once again, this means that a subsequence of the iterates will converge to a KKT point [58–61].

Overall, the convergence results for GSS methods applied to linearly constrained minimization are comparable to those for gradient projection methods. In addition to convergence to KKT points one can also prove that GSS methods have active set estimation properties comparable to those of gradient projection [60].

Nonsmooth (Lipschitz) Optimization

Because direct search methods do not explicitly rely on derivatives, they are useful for noisy optimization problems in which the objective and constraints may be viewed as smooth functions with small amplitude and high-frequency noise superimposed. Given their derivative-free nature it is natural to consider direct search methods for optimization of nonsmooth but Lipschitz continuous

functions. In many of these problems, the loci of nondifferentiability are more structured and, if one can take advantage of this structure, then it is possible to treat such problems effectively using direct search [62–65]. Unfortunately, in the general case, structured loci of nondifferentiability tend to cause trouble for direct search methods [66]. The descent-based searches conducted by direct search methods frequently lead the search to regions of nondifferentiability. In these regions the set of descent directions is no longer a half-space but a proper convex cone and there may fail to be a search direction inside this cone. As a consequence, direct search methods can stall away from a stationary point and be difficult to restart successfully, even for convex functions (see Ref. 5, Section 6).

General Nonlinear Constraints

Finally, consider the general nonlinear programming problem:

$$\begin{aligned} &\text{minimize } f(x) \\ &\text{subject to } h(x) = 0 \\ &\quad g(x) \leq 0. \end{aligned} \tag{4}$$

Direct search methods for general nonlinear programming can be devised by applying direct search methods for unconstrained or linearly constrained optimization to approaches based on penalization. Examples include quadratic penalization, logarithmic and reciprocal barrier methods, and augmented Lagrangian methods [67–71].

Constraints may also be treated by applying a direct search method to an exact, nonsmooth penalty function. This approach has the potential difficulties associated with applying direct search to nonsmooth optimization, and the algorithm may fail to converge to a stationary point, as discussed in the section titled “Nonsmooth (Lipschitz) Optimization”. One way to ameliorate this difficulty is to conduct multiple simultaneous searches with a mixture of smooth and nonsmooth penalty functions [72, 73]. By sharing information between the searches, one can avoid stalling due to nonsmoothness

by allowing the search to jump past regions of nondifferentiability.

There also exist direct search methods for the case where the derivatives of the nonlinear constraints are available, or where estimation of these derivatives is deemed appropriate. These methods make explicit use of derivatives of the constraints to compute feasible directions at the boundary of the feasible region. The feasible region near the current iterate is approximated by the linearization of the nearby constraints, as in traditional feasible directions methods that rely on derivatives. The important search directions are the generators of the cones polar to the cones generated by the nearby outward-pointing normals, as in the linearly constrained case. Examples of such methods include that of Klingman and Himmelblau [74] and Glass and Cooper [75]. More recently, Lucidi *et al.* [61] presented a feasible directions method that uses linearization to approximate constraints but applies direct search to the objective. A restoration step is used to ensure feasibility, and convergence to KKT points can be shown under mild conditions.

Finally, there are numerous direct search approaches to constrained optimization that apply heuristics to deal with constraints. For instance, in Box's Complex method [76], one of the earliest direct search methods designed to address problems with constraints, the objective is sampled at a broader set of points than in simplex-based methods in an attempt to avoid premature termination. Another approach is to interpret constrained optimization as a bilevel problem of improving feasibility and then optimality. The flexible tolerance method [77,78] alternately attempts to reduce the objective and constraint violation, depending on the extent to which the iterates are infeasible. A similar view motivated the adaptation of the filter method [79] to direct search [80].

STRENGTHS OF DIRECT SEARCH METHODS

Direct search methods for unconstrained and bound minimization are, in general, easy to describe and easy to implement. Methods for

linearly constrained optimization are more complex, but the ideas are familiar ones from linear programming or feasible directions methods.

GSS methods also enjoy theoretical guarantees of convergence to (constrained) stationary points that are similar to those for methods based on steepest descent. This perhaps surprising discovery has renewed interest in direct search methods in the mathematical optimization community [81].

Direct search methods are useful in problems where derivatives of the objectives or constraints are not available or not reliable. This situation can arise, for instance, when the evaluation of the objective or constraints involves computer calculations that exhibit a lack of smoothness due to features such as look-up tables, if-then-else logic, or the use of adaptive or iterative techniques. Problems in which evaluation of the objective involves experimentation (e.g., wind tunnel evaluation of drag [82]) are another place where derivatives are problematic.

Direct search methods can be applied in situations where there is no explicit numerical objective being optimized since they require only the ability to decide whether one set of decision variables is better than another. Such situations arise when the optimization involves subjective comparisons of "better" and "worse," as in the hearing aid tuning application mentioned previously [9]. Multiobjective optimization is another application that can be posed in this way [83].

There are many opportunities for scalable computational parallelism with direct search methods. Two successful parallel implementations of GSS are APPSPACK [84–86] for linearly constrained minimization and its successor HOPSPACK [72,73] for general nonlinearly constrained minimization.

WEAKNESSES OF DIRECT SEARCH METHODS

Direct search methods typically make rapid initial progress toward the solution. In this way they behave like steepest descent. However, convergence to a minimizer will only become apparent as the algorithm reduces the length of the trial steps. This means that

while a direct search algorithm may quickly approach a minimizer, it may be slow to detect this fact. This is the price of not explicitly using gradient information. Similarly, direct search methods may end up taking very small steps in regions where the objectives or constraints are highly nonlinear if no use is made of curvature (i.e., second derivative) information. It should be noted, however, that methods such as steepest descent or Newton's method can suffer from similar problems (if finite differences are used in Newton's method to estimate derivatives).

Direct search methods are also limited with respect to the size of the problems they can solve. They can be successfully applied to problems with a few hundreds of decision variables, but they cannot handle problems with many hundreds or thousands. This curse of dimensionality is due to the difficulty in obtaining sufficiently dense sets of search directions as the dimension increases.

In addition, many of the classical direct search methods, such as the simplex methods of Spendley *et al.* [47] and Nelder–Mead [4], do not enjoy theoretical guarantees of convergence when $n > 1$. For instance, the Nelder–Mead simplex algorithm can be shown to fail in theory [48] and is known to stall sometimes in practice.

DISCRETE OPTIMIZATION WITH NOISY OBJECTIVE FUNCTION MEASUREMENTS

Stacy D. Hill
The Johns Hopkins University,
Applied Physics Laboratory,
Laurel, Maryland

Discrete optimization with “noisy” objective function measurements—also referred to as *discrete (parameter) stochastic optimization*—is concerned with maximizing (or minimizing) real-valued functions defined on discrete sets, where the values of the objective function are unknown but can be estimated to within some measurement noise.

Some applications that give rise to the problem of optimizing noisy objective functions are: message transmission in communications networks [1–4]; locating a service or resource facility, such as a manufacturing warehouse, supply distribution center, school, or hospital [5,6]; scheduling machine usage in a production plant [7,8]; allocating people to evacuation routes [9]; and, more generally, allocating a finite number of units of a fixed resource to users or activities so as to minimize a given performance measure [10–12].

The salient feature of such optimization problems—which is a major source of difficulty—is the discreteness of the feasible region on which the objective function is defined. In contrast to continuous parameter optimization, objective functions defined on discrete sets lack derivatives that provide information about local optimality and guide the search for the optimum. The optimization of discrete functions relies on comparing differences of the objective function values, which must be estimated when those values contain noise.

This article will describe the general problem of stochastic discrete optimization and discuss characteristics and properties of several main approaches to solving it.

PROBLEM FORMULATION

Preliminaries

Although there is no generally accepted definition of what is meant by a discrete feasible region in optimization, usages of the term imply that the set is at most countable. Cardinality alone, however, does not suffice to describe discrete sets. (For example, rational numbers are at most countable but are not discrete.) In the case of optimization over subsets of real d -dimensional space, the common interpretation of a discrete set is that its points are separated by some fixed positive distance. An essential property of such sets is that functions defined on them lack derivatives. One way to guarantee that a derivative is undefinable is to require that the set have no accumulation points. This observation motivates the following topological definition of discreteness (see, e.g., [13]), which suffices for the discussion in this article and is sufficiently general to cover most problem settings.

A set in a topological space is discrete if it has no accumulation points. Equivalently, a discrete set is one that contains only isolated points. For example, the integers $\mathbb{Z}$ form a discrete set in the reals $\mathbb{R}$, whereas the set of rational numbers do not.

The introduction of a topology, aside from its usefulness in defining discreteness, simplifies the discussion of convergence concepts. In particular, a sequence of points $\{\theta_n\}$ in a discrete set Θ converges to a point θ in Θ if $\theta_n = \theta$ for n sufficiently large. (Take any neighborhood of θ containing no point of Θ other than θ . Such neighborhoods exist because discrete sets contain only isolated points.) Similarly, θ_n converges to a subset E of Θ , consisting of finitely many points, if $\theta_n \in E$ for sufficiently large n .

The Optimization Problem

The discrete stochastic optimization problem has the following general formulation. Let L

be a real-valued *objective function* defined on a discrete, at most countable feasible region Θ —the problem domain. The value $L(\theta)$ is unknown, but it is assumed that, for each $\theta \in \Theta$, there is available a random variable $Y = Y(\theta)$ such that

$$Y = L(\theta) + \varepsilon(\theta), \quad \theta \in \Theta, \quad (1)$$

where $\varepsilon(\theta)$ —measurement or estimation noise—is a random variable with mean zero. Thus, $Y(\theta)$ satisfies $L(\theta) = \mathbb{E}[Y(\theta)]$, for each θ . The problem is to find $\theta^* \in \Theta$ such that

$$L(\theta^*) = \min_{\theta \in \Theta} L(\theta) \quad (2)$$

using only measurements of Y . To avoid trivialities, it is assumed throughout this article that Θ is nonempty and, furthermore, that L is nonconstant on Θ .

The objective function will sometimes be interpreted as measuring some type of loss, such as cost. The problem, then, is to find points in the feasible region that minimizes loss. Note that the problem of minimizing $L(\theta)$ is equivalent to the problem of maximizing $-L(\theta)$. In addition, any method for finding a maximum is, therefore, easily modified to yield a method for finding a minimum. The choice of problem—minimization or maximization—is a matter of convenience and, usually, is dictated by the particular application. The choice here is to view optimization as minimization (of loss) unless otherwise stated.

Let Θ^* denote the set consisting of all points in Θ that solve Equation (2), that is, the set consisting of the points in Θ that *optimize* L . When Θ is finite, Θ^* is nonempty (because it is assumed that Θ is nonempty). When Θ is infinite, it will be assumed that Θ^* is nonempty. In either instance, the minimum value of $L(\theta)$ exists and will be denoted by L^* .

It is tempting to view discrete optimization problems as optimization over $\mathbb{Z}$, as any function defined on a discrete set can be transformed into a function on a subset of integers and minimized there. (For example, if h is a one-to-one correspondence between Θ and a subset J of $\mathbb{Z}$, define the loss function on J to be $\tilde{L}(z) = L(h(z))$ for each z in

J .) However, there may be little or no benefit in doing so. In fact, the transformed problem might eliminate some inherent problem structure (e.g., property of the objective function) that aids in the problem solution. A simple example of this is the discrete resource allocation problem [11]. The problem is to distribute a finite resource to a finite number of users so as to minimize some allocation cost that is assumed to be discretely convex (see, e.g., [14]). If d is the number of users, then the feasible region is a subset of $\mathbb{Z}_+^d$, the set of points in $\mathbb{R}^d$ with nonnegative integer coordinates, where the coordinates represents the amount of resource allocated to each user. There are infinitely mappings that define a one-to-one correspondence between $\mathbb{Z}_+^d$ and $\mathbb{Z}$, but there is no guarantee that any one of them will preserve the convexity of the cost function in the original problem. Thus, the formulation and representation of a problem requires some care. (For discussion of issues associated with problem formulation, see, e.g., [15,16].)

OPTIMIZATION APPROACHES

It is worth noting that deterministic optimization algorithms do not generally apply to noisy objective functions as they rely on the values of $L(\theta)$ in the search for an optimum. Such algorithms assume that Y contains no measurement noise and, therefore, assume—erroneously—that a small value of $Y(\theta)$ necessarily corresponds to a small value of $L(\theta)$. Thus, deterministic methods seek points in the feasible region that minimize $Y(\theta)$ and, therefore, do not apply without some modification.

There is a vast literature on optimizing discrete objective functions with noise. This section highlights aspects of several classes of solution approaches that encompass a broad range of techniques. These include statistical approaches, random search methods, stochastic approximation (SA), and sample path methods. Unless otherwise stated, it will be assumed that Θ is finite. The case in which Θ is infinite will be discussed later.

Statistical Approaches

Statistical optimization methods make decisions about which parameter values are the best typically in terms of hypothesis testing procedures or confidence intervals. The methods include ranking and selection (R&S) and multiple comparisons (e.g., [17–22]) and adaptive allocation or sequential design of experiments (see, e.g., [23–25]). Spall [Chap. 12, Ref. 26] discusses the application of R&S and multiple comparisons to discrete stochastic optimization, with worked examples.

Statistical procedures treat the objective function values as the unknown parameters corresponding to k statistical populations, $1 < k < \infty$. The i th population, $i = 1, 2, \dots, k$, has probability density function $f(y; \theta(i))$ (with respect to some dominating probability measure ν , say) and mean $L_i = L(\theta(i))$. The form of $f(\cdot; \theta(i))$ is assumed known, where $\theta(i)$ is a fixed but unknown parameter. Thus, Θ is the set consisting of the points $\theta(1), \theta(2), \theta(3), \dots, \theta(k)$. The populations are ranked according to the L_i values, where the smaller values determine the better ranks, with L^* being the smallest of the L_i 's. The problem is to construct procedures for identifying the best-ranked population by taking observations of the random variables $Y(\theta(i))$.

Ranking and Selection, Multiple Comparison. These methods make decisions regarding the best in terms of independent observations of Y , where n_i independent identically distributed (i.i.d.) observations are taken of $Y(\theta(i))$, $i = 1, 2, 3, \dots, k$. Inference is based on the sample means of the $Y(\theta(i))$'s.

R&S methods are decision rules for selecting a single population or a subset of populations (of fixed or random size) such that the selection includes the best-ranked population with probability at least equal to P^* . The probability of obtaining a correct selection, P^* , is specified before selection. A variant of such procedures is the selection of a subset that includes the best population, with probability of at least P^* , when the parameters satisfy some other condition (such as the condition that the difference between the best

and the next best value be greater than or equal to some specified value).

Multiple comparison procedures rely on simultaneous confidence intervals to select the best population. An example of this type of procedure is the construction of simultaneous confidence intervals about the differences between the values of the objective function, $L_i - L_j$, where $i \neq j$, such that each interval is of the same confidence level. Confidence intervals about the differences between objective function values facilitate inference about the magnitudes and directions of the differences and, consequently, enable inferences about the best value of $L(\theta)$. Similar to R&S, the confidence intervals are constructed by taking i.i.d. samples of $Y(\theta(i))$, for each i .

Some useful measures of performance of these statistical procedures are the expected size and the expected sum of ranks of the selected subset (for R&S procedures) and the expected width of the confidence intervals (for the multiple comparison procedures). For example, consider the problem of selecting a set that contains the best-ranked population with probability P^* . The size of the selected set is a random variable S such that $1 \leq S \leq k$. Suppose that the decision rule selects population i for inclusion in the set by comparing estimates of the $\hat{L}(\theta)$'s defined to be the sample means of the observed values of $Y(\theta)$. Suppose that i is included if

$$\hat{L}(\theta(i)) \leq \min\{\hat{L}(\theta), \theta \in \Theta\} + d \quad (3)$$

where d is chosen so that the set contains L^* with probability P^* . The expected value of S is given by

$$E(S) = \sum_{i=1}^k P(\text{Selecting the population of rank } i). \quad (4)$$

It is also of interest to consider under what conditions on the L_i values, for example, is the maximum value of $E(S)$ achieved.

Sequential Design. The method of optimization by sequential design (initiated in Ref. [23]) sequentially samples $y_1, y_2, y_3, \dots$ from k populations, where y_i is drawn from population m_i . The problem is to select the populations from which to sample the

observations so as to optimize the expected value of the sum $S_n = y_1 + y_2 + y_3 + \dots + y_n$ as $n \rightarrow \infty$. (In this section, optimization will be taken to be maximization, in order to keep with the literature on this problem. Thus, L^* , here, denotes the maximum value of L .)

The choice of population from which to sample the n th observation y_n is a “decision” φ_n such that the event $\{\varphi_n = i\}$, $1 \leq i \leq k$, “sample the n th observation y_n from population i ,” depends only on $\varphi_1, y_1, \dots, \varphi_{n-1}, y_{n-1}$, $n = 1, 2, 3, \dots$. The sequence of decisions defines a sequential experimental design $\varphi = (\varphi_1, \varphi_2, \varphi_3, \dots)$. If

$$\lim_{n \rightarrow \infty} \frac{E(S_n)}{n} = L^*, \quad (5)$$

then φ is said to be consistent.

Robbins [23] developed consistent sequential experimental designs for the case $k = 2$. Robbins and Lai [24] consider the general case, $k \geq 2$.

The problem of maximizing $E(S_n)$ is equivalent to minimizing the *regret* ([24])

$$R_n = nL^* - E(S_n) = \sum_{i: L(\theta_i) < L^*} (L^* - L_i) E T_n(i), \quad (6)$$

where $T_n(i)$ is the number of times, within the first n observations, that φ samples from population i .

Lai and Robbins [24] call a decision rule *asymptotically efficient* if its regret satisfies $R_n = o(n^\beta)$, for every $\beta > 0$. They show how to construct asymptotically efficient rules that asymptotically satisfy

$$E T_n(i) \sim (\log n) / I(\theta(i); \theta^*) \quad (7)$$

for each $\theta(i)$ such that $L_i < L^*$, where $I(\theta, \lambda)$ denotes the Kullback-Leibler number

$$I(\theta, \lambda) = \int [\log (f(y; \theta) / f(y; \lambda))] f(y; \theta) \, d\nu(y).$$

The interpretation of (7) is that an asymptotically efficient rule takes about $(\log n) / I(\theta(i); \theta^*)$ observations from an inferior population. A consequence of (6) and (7)

is that such rules satisfy

$$R_n \sim \left\{ \sum_{i: L_i < L^*} (L^* - L_i) / I(\theta(i); \theta^*) \right\} \log n, \quad (8)$$

which provides a measure of expected long run performance.

Lai [25] discusses generalizations of the problem studied in Ref. [24] and discusses applications to engineering and economics.

Random Search

Optimization by random or stochastic search is similar in spirit to the method of sequential design. Random search algorithms produce a sequence $\hat{\theta}_1, \hat{\theta}_2, \hat{\theta}_3, \dots, \hat{\theta}_n$ of estimated solutions to Equation 2 such that the next estimate $\hat{\theta}_{n+1}$ is obtained by searching for candidate points “near” $\hat{\theta}_n$, according to some specific random procedure. The goal is to obtain estimates $\hat{\theta}_n$ that converge, in some sense, to the optimizing set Θ^* .

In general terms, random search iteratively selects a candidate value for updating the current solution estimate. Candidate values are chosen from the set of “neighbors” of the current value. The candidate value is compared to the current solution estimate in some particular manner and, depending on the outcome of the comparison, the candidate value either replaces the current solution estimate (and becomes the new value of the estimate) or is discarded, in which instance, the current value of the estimate is retained. The procedure is repeated to obtain the next estimate and, thereby, generate a sequence of solution estimates.

Search methods differ in several ways: the set of points that are considered neighbors of a given point, the random mechanism for selecting candidate values from among the neighbors of a given point, the procedure for comparing the candidate and current values of the estimates, and the criterion for accepting the candidate as the new solution estimate. The convergence properties of the solution estimates vary depending on the method.

The general steps of random search algorithms are outlined below. For each $\theta \in \Theta$, there is a nonempty set $N(\theta) \subset \Theta \setminus \{\theta\}$, called

the set of *neighbors* of θ , from which solution candidates are chosen when the current solution estimate is θ . A candidate value θ' is chosen from $N(\theta)$ with (conditional) probability $R(\theta, \theta')$. The next step is to decide whether to accept the candidate as the new solution estimate or reject it, in which instance, there is no change and the current estimate is taken to be the new estimate.

The sets of neighbors, it is assumed, are constructed in such a way that all points in Θ are *reachable* from one another. (This assumption ensures that every point in Θ is chosen as a candidate during the search for the optimum.) For a point θ' to be reachable from θ , there must be a finite sequence $\theta_0, \theta_1, \dots, \theta_l$ in Θ , for some integer $l \geq 1$, such that $\theta_0 = \theta, \theta_l = \theta'$ and, for $i = 0, 1, \dots, l-1$, the point θ_{i+1} belongs to the set of neighbors of θ_i . The smallest such l is the *distance* between θ and θ' .

The function $R(\cdot, \cdot)$, called the *transition probability* for Θ , satisfies

$$\sum_{\theta' \in N(\theta)} R(\theta, \theta') = 1, \quad (9)$$

and $R(\theta, \theta') > 0$ if and only if $\theta' \in N(\theta)$. The transition probability for Θ and neighbor sets are assumed to be symmetric, that is, $R(\theta, \theta') = R(\theta', \theta)$ and $\theta' \in N(\theta)$ if and only if $\theta \in N(\theta')$, for all θ, θ' belonging to Θ . It is sometimes convenient (as in Refs. [27–29]) to relax the requirement that R be symmetric and define it in terms of an unnormalized symmetric function R' , where

$$R(\theta, \theta') = \frac{R'(\theta, \theta')}{D(\theta)} \quad (10)$$

and the denominator $D(\theta) = \sum_{\theta' \in N(\theta)} R'(\theta, \theta') > 0$ for each θ in Θ . A simple example of an unnormalized function is $R'(\theta, \theta') = 1$ if and only if θ' belongs $N(\theta)$. The denominator $D(\theta)$ is then equal to the number of points in $N(\theta)$.

The estimates $\hat{\theta}_n$ in general random search algorithms are obtained as follows:

General Random Search Algorithm

Step 1: Pick an initial value $\hat{\theta}_0$ for the estimate. Initialize counter: $n = 0$.

Step 2: Given $\hat{\theta}_n$, choose a candidate new value for the solution $\theta'_n \in N(\hat{\theta}_n)$, with probability $R(\hat{\theta}_n, \theta'_n)$.

Step 3: Using samples of $Y(\theta'_n)$ and possibly $Y(\hat{\theta}_n)$, given θ'_n and $\hat{\theta}_n$, decide whether to accept or reject θ'_n as the new estimate. If accepted, put $\hat{\theta}_{n+1} = \theta'_n$; otherwise $\hat{\theta}_{n+1} = \hat{\theta}_n$.

Step 4: Increment counter, $n = n + 1$ and go to step (2).

Several methods that highlight random search approaches are the stochastic ruler, stochastic comparison, and simulated annealing (SAN) with noise.

Stochastic Ruler. Yan and Mukai [30] convert problem (2) into a maximization problem in which candidate solutions θ' are evaluated by comparing estimates of their loss function values $L(\theta')$ with an absolute scale. Candidate values are accepted if, with high probability, their loss function estimates are small compared with the scale value. The “scale” against which comparisons are made is a uniformly distributed random variable.

Yan and Mukai [30] showed that if U is uniformly distributed over (a, b) , then every solution to the following maximization problem solves the original minimization problem (2):

$$\max P\{Y(\theta) \leq U\}, \quad \theta \in \Theta, \quad (11)$$

provided that (a, b) is sufficiently large. The only assumption here, in addition to Θ being a finite set, is that, for each $\theta \in \Theta$, $Y(\theta)$ is independent of U and has a finite second moment. In addition, if the $Y(\theta)$'s are uniformly bounded random variables, then a and b can be taken to be any pair of upper and lower bounds.

In step (3) of the general random search algorithm, the original stochastic ruler method [30] uses estimates of the probability that $Y(\theta') \leq U$, given $\theta'_n = \theta'$ and current estimate $\hat{\theta}_n = \theta$, in the decision to accept or reject the current estimate. More precisely, given $\hat{\theta}_n = \theta$ and $\theta'_n = \theta'$, define $\hat{\theta}_{n+1}$ so that

$$\hat{\theta}_{n+1} = \begin{cases} \theta', & \text{with probability } p_n(\theta'_n), \\ \theta, & \text{with probability } 1 - p_n(\theta'_n), \end{cases} \quad (12)$$

where

$$p_n(\theta') = (\mathbb{P}\{Y(\theta') \leq U\})^{M_n} \quad (13)$$

and M_n is a fixed positive integer depending on n . The probability p_n is estimated using up to M_n samples of Y .

The sequence $\{\hat{\theta}_n\}$ is a nonstationary, irreducible Markov chain with state space Θ . Yan and Mukai [30] showed that $\hat{\theta}_n$ converges to the set Θ^* in probability, that is,

$$\lim_{n \rightarrow \infty} \mathbb{P}\{\hat{\theta}_n \in \Theta^*\} = 1, \quad (14)$$

if the sequence of positive integers $M_n \rightarrow \infty$ at rate $\log n$. In fact [Thm. 7.1 of Ref. 30],

$$M_n \sim C \log n \quad \text{as } n \rightarrow \infty, \quad (15)$$

where the constant $C > 0$ depends on the distances between points and the comparison probabilities $\mathbb{P}\{Y(\theta) \leq U\}$, $\theta \in \Theta$.

An obvious drawback of the stochastic ruler method is that M_n increases with n , which implies that the estimate of p_n in (13) requires an increasing number of samples of Y with increase in iteration. Alrefaei and Andradottir [27–29] developed modified versions of the stochastic ruler method in which M_n in (13) is constant. (In Ref. [28], the feasible region Θ is allowed to be countably infinite.)

The modified stochastic ruler methods differ from the original method of Yan and Mukai [30] in two key ways. First, the acceptance probability in the modified method is

$$p_n(\theta) = (\mathbb{P}\{Y(\theta) \leq U\})^M \quad (16)$$

where M is a fixed positive integer. Thus, unlike the acceptance probability (13) in the original method, the number of samples of Y required to estimate the probability p_n does not grow with n .

Second, the modified methods introduce an intermediate step in the decision to accept or reject a candidate solution. This decision generates a sequence $\{\tilde{\theta}_n\}$, which is then used to define the estimates $\hat{\theta}_n$ as a subsequence of $\{\tilde{\theta}_n\}$. To be explicit, initialize the algorithm with $\tilde{\theta}_0 \in \Theta$ and suppose that $\tilde{\theta}_n$ has been defined. Given $\tilde{\theta}_n$, choose θ'_n from $N(\tilde{\theta}_n)$ with

probability $R(\tilde{\theta}_n, \theta'_n)$. Given $\theta'_n = \theta'$ and $\tilde{\theta}_n = \tilde{\theta}$, the next value $\tilde{\theta}_{n+1}$ is defined by putting

$$\tilde{\theta}_{n+1} = \begin{cases} \theta', & \text{with probability } p_n(\theta'), \\ \tilde{\theta}, & \text{with probability } 1 - p_n(\theta'). \end{cases} \quad (17)$$

The estimates $\hat{\theta}_n$ are obtained as an embedded Markov chain that is defined by extracting a particular subsequence of $\{\tilde{\theta}_n\}$. Put $\hat{\theta}_0 = \tilde{\theta}_0$. Suppose that $\hat{\theta}_n$ has been defined. The decision whether or not to choose $\tilde{\theta}_{n+1}$ as the next value $\hat{\theta}_{n+1}$ or take $\hat{\theta}_{n+1}$ to be the current value $\hat{\theta}_n$ is based on the number of times that the Markov chain visits the two state values through the first n iterations. To be more precise, let $V_n(\theta)$ denote the number of times the Markov chain $\{\tilde{\theta}_n\}$ “visits” state θ in the first n steps. Thus, $V_n(\theta) = \#\{i : \tilde{\theta}_i = \theta, i = 1, 2, 3, \dots, n\}$. Put

$$\hat{\theta}_{n+1} = \begin{cases} \tilde{\theta}_{n+1}, & \text{if } V_{n+1}(\tilde{\theta}_{n+1})/D(\tilde{\theta}_{n+1}) \\ & > V_{n+1}(\hat{\theta}_n)/D(\hat{\theta}_n), \\ \hat{\theta}_n, & \text{otherwise.} \end{cases} \quad (18)$$

The function D , recall, is defined in Equation 10. State visits V_n are defined in terms of $\{\tilde{\theta}_n\}$ as follows. For $n = 0$, set $V_0(\theta) = 1$ if $\theta = \tilde{\theta}_0$; otherwise, $V_0(\theta) = 0$. Having defined $V_n(\theta)$, for $n \geq 1$, let

$$V_{n+1}(\theta) = \begin{cases} V_n(\theta) + 1, & \text{if } \theta = \tilde{\theta}_{n+1}, \\ V_n(\theta), & \text{otherwise.} \end{cases}$$

Alrefaei and Andradottir [29] considered variants of (18), which differ depending on how V_n is defined. Each of the modified stochastic ruler methods define $\{\hat{\theta}_n\}$ to be some subsequence of $\{\tilde{\theta}_n\}$.

The modified stochastic ruler has stronger convergence properties than the original. The modified method produces a stationary Markov chain such that [29]

$$\mathbb{P}\{\lim_{n \rightarrow \infty} \hat{\theta}_n \in \Theta^*(a, b)\} = 1. \quad (19)$$

In other words, the sequence of estimates in the modified method converge almost surely (a.s.). Wang [31] contains a comprehensive analysis of the rate of convergence of the stochastic ruler method and the stochastic comparison method discussed in the next

section. In addition, see [29] for rate of convergence results.

Stochastic Comparison. Stochastic comparison [32] is similar to the stochastic ruler method in that it replaces the minimization problem [Equation (2)] with a maximization problem that involves comparing random variables. In this method, each $Y(\theta)$ is compared, in probability, with all other $Y(\theta')$, $\theta' \neq \theta$. This comparison probability, denoted $\text{sp}(\theta)$, is called the *sigma-probability* corresponding to θ . Any θ that maximizes the sigma-probability over Θ solves the minimization problem [Equation (2)].

The sigma-probability is defined by

$$\text{sp}(\theta) = \sum_{\theta' \neq \theta} \mathbb{P}\{Y(\theta) < Y(\theta')\}, \quad \theta \in \Theta. \quad (20)$$

Gong *et al.* [32] showed that, if the measurement noises $\varepsilon(\theta)$ in (1) are i.i.d., zero mean, and have symmetric continuous probability density functions for every θ in Θ , then any point θ that maximizes $\text{sp}(\theta)$ over Θ solves the minimization problem [Equation (2)] and conversely.

The implementation steps of stochastic comparison are the same as the stochastic ruler but with a different acceptance probability. Given $\hat{\theta}_n = \theta$ and $\theta'_n = \theta'$, the following acceptance probability replaces (13)

$$p_n(\theta') = (\mathbb{P}\{Y(\theta') < Y(\theta)\})^{M_n}. \quad (21)$$

As in (13), this probability is estimated using up to M_n samples of $Y(\theta')$ and $Y(\theta)$.

Stochastic comparison yields a sequence of estimates $\hat{\theta}_n$ that converge in probability to Θ^* . The proof of convergence ([32]) is along the same lines as that for the stochastic ruler. (See [31] for rate of convergence analysis.)

Simulated Annealing. SAN for objective functions with noise is considered in [Section 8.2.2 of Ref. 26] and Refs. [33–37]. In terms of the general random search algorithm, SAN for noisy loss functions takes the following form. Given $\hat{\theta}_n = \theta$, choose θ'_n from $N(\theta)$ with probability $R(\theta, \theta'_n)$ in step (2). The decision

step (3) is, given $\hat{\theta}_n = \theta$ and $\theta'_n = \theta'$,

$$\hat{\theta}_{n+1} = \begin{cases} \theta', & \text{with probability } p_n(\theta', \theta), \\ \theta, & \text{with probability } 1 - p_n(\theta', \theta). \end{cases} \quad (22)$$

In this instance, the acceptance probability is

$$p_n(\theta', \theta) = \exp \left\{ \frac{-[\hat{L}(\theta') - \hat{L}(\theta)]^+}{T_n} \right\}, \quad (23)$$

where T_n is the usual *temperature* parameter, $\hat{L}(\theta')$ and $\hat{L}(\theta)$ are sample means of $Y(\theta')$'s and $Y(\theta)$'s, respectively, based on samples of sizes, say, k_n and k'_n , respectively, and $\alpha^+ = \max\{\alpha, 0\}$. The acceptance probability (23) is

$$p_n(\theta', \theta) = \exp \left\{ \frac{-[L(\theta') - L(\theta) + w_n]^+}{T_n} \right\}, \quad (24)$$

where w_n is the difference of the noise terms in the estimates of $L(\theta')$ and $L(\theta)$.

The assumptions in Refs. [33–35] on the transition probability $R(\cdot, \cdot)$ and temperature sequence $\{T_n\}$ is that convergence holds for the “undisturbed” SAN sequence, that is, the sequence of estimates $\hat{\theta}_n$ obtained by setting $w_n = 0$ in (24).

SAN algorithms differ depending on assumptions made about the temperature sequence $\{T_n\}$, the noise in (1) [and, hence, in (24)] and the estimates of the objective function values. For example, Gelfand and Mitter [33] showed that, if $T_n \rightarrow 0$ and if the noise w_n in (24) is Gaussian with mean zero noise and standard deviation $\sigma_n = o(T_n)$, then $\hat{\theta}_n$ converges to Θ^* in probability if and only if convergence in probability holds for the “undisturbed” SAN sequence. A consequence of the assumption $\sigma_n = o(T_n)$ is that $k'_n, k_n \rightarrow \infty$, so that the number of samples required to for the estimates $\hat{L}$ in (23) increases with iteration.

Gutjahr and Pflug [35] relaxed the Gaussian assumption in Ref. [33] on w_n by assuming only that the noise distribution is more concentrated or “peaked” about the origin than a Gaussian distribution with mean zero and standard deviation $\sigma_n = O(n^{-\alpha})$, where $\alpha > 1$ and $\sigma_n > 0$.

In other words, Thm. 4.1(ii) of Ref. 35 assumes that

$$P\{|w_n| \geq t\} \leq \int_{-t}^t \frac{1}{\sqrt{2\pi}\sigma_n} \exp\left\{\frac{-x^2}{2\sigma_n^2}\right\} dx$$

for each $t \geq 0$ (i.e., the tail probabilities of the $N(0, \sigma_n^2)$ distribution dominate those of w_n).

The SAN algorithms by Alrefaei and Andradottir [37] seem to be the most practical in terms of implementation and yield strong convergence. They introduced modified SAN algorithms that relax the assumption that $T_n \rightarrow 0$, requiring only that the temperature T be a (strictly) positive constant. Their algorithms are similar to their embedded Markov chain algorithms for the stochastic ruler in Refs. [27–29]. The modified SAN algorithms in Ref. [37] produce estimates that converge a.s. to the set of loss function optimizers. The rate of convergence of this algorithm is considered in Ref. [36], which also examines the convergence rate for the modified stochastic ruler method.

Stochastic Approximation

SA refers to a class of recursive algorithms for solving two types of problems: finding roots and minima (or maxima) of noisy objective functions, where Θ is a subset of $\mathbb{R}^d$. There is a well-established SA literature for continuous parameter problems, beginning with the seminal works of Robbins and Monro [38] and Kiefer and Wolfowitz [39]. (See Chaps. 4–7 of Ref. 26 or Ref. 40 for surveys of SA methods.)

The general form of SA is

$$\hat{\theta}_{n+1} = \hat{\theta}_n - a_n \hat{g}_n(\hat{\theta}_n). \quad (25)$$

In continuous parameter minimization, the loss function L is assumed to be differentiable and $\hat{g}_n(\theta)$ is an estimate of its gradient $g(\theta)$. For the problem of finding the root of an unknown function, which is the classical SA setting of Robbins and Monro [38], the term $\hat{g}_n(\theta)$ is an estimate of the unknown function and is assumed to be unbiased. In all SA procedures, the *gain sequence* $\{a_n\}$ is a sequence of positive numbers such that $a_n \rightarrow 0$ and

$$\sum_n a_n = \infty. \quad (26)$$

In Robbins-Monro SA, the gain sequence also satisfies

$$\sum_n a_n^2 < \infty. \quad (27)$$

Kiefer-Wolfowitz SA, where the goal is to minimize an unknown function, imposes additional assumptions on the gain sequence. In this latter SA setting, the gradient estimate $\hat{g}_n(\theta)$ is biased and is obtained from noisy estimates of the loss.

If the loss function has a unique minimizer, then minimizing point θ^* is the root of the gradient. The goal, then, is to obtain a sequence $\{\hat{\theta}_n\}$ that converges a.s. or, more generally, in probability to the minimizing value of the loss.

Dupač and Herkenrath [41] considered the problem of finding the root of an unknown vector-valued function $g(\theta)$, defined on a lattice type discrete set Θ in $\mathbb{R}^d$ such as $\mathbb{Z}^d$. (A discrete subset of $\mathbb{R}^d$ is a lattice if it is an infinite set and the distance between pairs of points that are nearest neighbors is bounded by a fixed, positive constant.) The problem is to find a point in Θ that minimizes $|g(\theta)|$ using only noisy measurements of $g(\theta)$. (In the continuous parameter setting, the problem is to find a root of $g(\theta)$.) They apply their root finding procedure to the problem of optimizing real-valued functions defined on a lattice.

The general root-finding approach in Ref. [41] is to transform the discrete problem into a continuous one by interpolating the discrete function to a continuous function defined over $\mathbb{R}^d$ and, then, apply the Robbins-Monro SA procedure to find a root of the interpolated function. The resulting SA sequence $\{\hat{\theta}_n\}$ does not necessarily lie in the lattice Θ . From this sequence, [41] constructs a lattice-valued sequence $\{\tilde{\theta}_n\}$ that has convergence properties similar to the original. In particular, when $\{\hat{\theta}_n\}$ converges to θ^* , so does $\{\tilde{\theta}_n\}$ and in the same mode.

The lattice-valued sequence $\{\tilde{\theta}_n\}$ has a simple form when Θ is the lattice $\mathbb{Z}$. Each $\hat{\theta}_n$ satisfies the inequality $\lfloor \hat{\theta}_n \rfloor \leq \hat{\theta}_n \leq \lceil \hat{\theta}_n \rceil$. Moreover, there are unique scalars $\lambda_1, \lambda_2 \geq 0$ (depending on $\hat{\theta}_n$) such that $\lambda_1 + \lambda_2 = 1$ and $\hat{\theta}_n = \lambda_1 \lfloor \hat{\theta}_n \rfloor + \lambda_2 \lceil \hat{\theta}_n \rceil$. Put

$$\tilde{\theta}_n = \begin{cases} \lfloor \hat{\theta}_n \rfloor & \text{with probability } \lambda_1, \\ \lceil \hat{\theta}_n \rceil & \text{with probability } \lambda_2. \end{cases} \quad (28)$$

In other words, $\tilde{\theta}_n$ is a random “projection” of $\hat{\theta}_n$ onto the lattice Θ .

The interpolations in Ref. [41] are piecewise linear interpolations constructed so that they satisfy the conditions of Robbins-Monro SA and have the same set of solutions as the functions that they interpolate. In the root finding problem, in particular, the estimate $\hat{g}_n(\theta)$ in (25) is defined so that it is an unbiased estimate of the interpolation $\bar{g}$ of the unknown function g . Thus,

$$\mathbb{E}[\hat{g}_n(\hat{\theta}_n) | \hat{\theta}_n] = \bar{g}(\hat{\theta}_n). \quad (29)$$

Dupač and Herkenrath [41] showed that their root finding procedure converges exponentially fast when Θ is a lattice type set in $\mathbb{R}$. In the real discrete setting, their Corollary 1 implies that there is a positive constant C such that

$$\mathbb{P}(|\hat{\theta}_n - \theta^*| > 1) \leq \exp(-Cn). \quad (30)$$

In terms of the lattice-valued projections $\tilde{\theta}_n$ of $\hat{\theta}_n$,

$$\mathbb{P}(\tilde{\theta}_n \neq \theta^*) \leq \exp(-Cn). \quad (31)$$

There are other examples of the use of continuous interpolation in discrete optimization, for example, Gokbayrak and Cassandras [42] (the “surrogate function” method) and Wang and Schmeiser [43]. Both Refs. [42] and [43] assume that the feasible region Θ is a subset of $\mathbb{R}^d$ and both linearly interpolate functions over simplexes. The resulting continuous optimization problem is then solved by means of standard SA methods. Finally, the estimates in the continuous parameter problem are projected onto closest point in the discrete region to obtain a sequence of estimates for the solution of the original discrete problem. Thus, if $\hat{\theta}_n$ is the estimated solution to the continuous problem, then its projection $\tilde{\theta}_n$ onto Θ is taken to be the estimated solution to the original discrete problem.

The linear interpolations in Refs. [42] and [43] are essentially Lovász extensions of a function (Refs. [44] and [45]), which depend on the representation of points in a simplex. The Lovász extension of L on the unit cube in $\mathbb{R}^d$ is obtained by linearly interpolating L piecewise at the vertices of each simplex

in a particular collection of simplexes. Each simplex has $d + 1$ vertices and is defined in terms of a permutation on d integers. If τ is such a permutation (there are $d!$ unique permutations on d integers), then the simplex S_τ defined by τ is the set consisting of all points $x = (x_1, x_2, \dots, x_d)$ in the unit cube such that $x_{\tau(1)} \leq x_{\tau(2)} \leq x_{\tau(3)} \leq \dots \leq x_{\tau(d)}$. Each point in a simplex can be uniquely expressed as a convex combination of the vertices. To be more precise, if the vertices of S_τ are denoted $v_0, v_1, v_2, \dots, v_d$, then, for each x in S_τ , there are $d + 1$ scalars $\lambda_i \geq 0$, $i = 0, 1, 2, \dots, d$, called *weights*, such that $\sum_{i=0}^d \lambda_i = 1$ and

$$x = \sum_{i=0}^d \lambda_i v_i. \quad (32)$$

Such representations are unique. Each point in the unit cube has a representation, as the $d!$ simplexes form a covering for the unit cube. The representation is extended to any point in $\mathbb{Z}^d$ in the obvious manner. The representation (32) leads to a natural extension of functions on $\mathbb{Z}^d$. If f is a function defined on the vertices of the unit cube, then the simplex representation of points leads to the following natural extension:

$$\tilde{f}(x) = \sum_{i=0}^d \lambda_i f(v_i) \quad (33)$$

where x is given by (32).

Gerencsér *et al.* [46,47], Hill *et al.* [48,49], and Hill [50] introduced an optimization approach similar to Refs. [2] and [43], where the discrete region is $\mathbb{Z}^d$. In Refs. [48–50], the objective function is assumed to be integer convex and separable ([14]). The implication of this assumption is that the discrete loss function can be viewed as the restriction of a piecewise linear, separable convex function defined on all of $\mathbb{R}^d$. Thus, the resulting SA algorithm is a Robbins-Monro type procedure for convex optimization Ref. [51] (Sec. 5.6), Ref. [52].

Because piecewise linear functions may fail to be differentiable at some points, subgradients rather than gradients should be

used in the search for the optimum. References [48–50] use efficient estimates of the subgradient to obtain a computationally efficient SA algorithm. The subgradient estimates use the computationally efficient simultaneous perturbation (SP) approximation developed by Spall [53] in his simultaneous perturbation stochastic approximation (SPSA) algorithm for continuous parameter optimization. This type of subgradient estimate, which leads to discrete SPSA (DSPSA), is the key difference between Refs. [48–50] and other works that rely on continuous interpolation of the loss function.

For scalar θ , the SP subgradient estimate is [see Equation 16 of Ref. 50] (making the obvious substitutions for θ , c , and Δ)

$$\hat{g}_n(\hat{\theta}_n) = \frac{\bar{Y}(\hat{\theta}_n + c_n \Delta_n) - \bar{Y}(\hat{\theta}_n - c_n \Delta_n)}{2c_n \Delta_n} \quad (34)$$

where $\bar{Y}$ is a piecewise linear interpolation of Y , $c_n > 0$, and Δ_n is a ± 1 Bernoulli random variable independent of measurement noise. For small enough c_n , this subgradient estimate reduces to

$$\hat{g}_n(\hat{\theta}_n) = \begin{cases} (\bar{Y}(\hat{\theta}_n + 1) - \bar{Y}(\hat{\theta}_n - 1))/2, & \text{when } \hat{\theta}_n \text{ is an integer,} \\ \bar{Y}(\lfloor \hat{\theta}_n \rfloor + 1) - \bar{Y}(\lfloor \hat{\theta}_n \rfloor), & \text{otherwise,} \end{cases} \quad (35)$$

where $\lfloor \theta \rfloor$ is the vector consisting of the floor of each component of θ . The subgradient estimate in (34) has the obvious extension to vector valued θ 's. Replace $\bar{Y}$ by its Lovász extension. Then, (34) becomes

$$\hat{g}_n(\hat{\theta}_n) = \frac{(\bar{Y}(\hat{\theta}_n + c_n \Delta_n) - \bar{Y}(\hat{\theta}_n - c_n \Delta_n))}{2c_n} \Delta_n^{-1} \quad (36)$$

where Δ_n^{-1} is formed by taking inverses component-wise.

It should be noted here that the subgradient estimate (36) differs from that in Refs. [48–50]. The SA algorithm in those works contain an incorrect subgradient estimate, which can lead to the nonconvergence of $\hat{\theta}_n$ to Θ^* that was noted in Ref. [54]. The subgradient estimate in Refs. [48–50] for scalar θ reduces to $\hat{g}(\theta) = Y(\lfloor \hat{\theta} \rfloor) - Y(\lfloor \hat{\theta} \rfloor - 1)$, which

has expected value $L(\lfloor \hat{\theta} \rfloor) - L(\lfloor \hat{\theta} \rfloor - 1)$. At noninteger values of $\hat{\theta}$, the difference $L(\lfloor \hat{\theta} \rfloor) - L(\lfloor \hat{\theta} \rfloor - 1)$ is not a subgradient of the (linear) interpolation of L . The correct subgradient at noninteger $\hat{\theta}$ is given by $L(\lfloor \hat{\theta} \rfloor + 1) - L(\lfloor \hat{\theta} \rfloor)$, as the interpolation of L is differentiable between successive integer points and subgradients reduce to the derivative where the latter exists.

The subgradient approximation (36) requires $d + 1$ evaluations of the loss for each θ . An alternative is to use a randomized Lovász extension to define $\bar{Y}(\theta)$ for arbitrary θ . (The idea is similar to that used in Ref. [41] to project the estimates $\hat{\theta}_n$ onto the lattice.) For each θ in $\mathbb{R}^d$, let $v_0, v_1, v_2, \dots, v_d$ be the vertices and $\lambda_0, \lambda_1, \lambda_2, \dots, \lambda_d$ the weights defined by the Lovász extension. Let $\tilde{\theta} = v_i$ with probability λ_i , and set $\bar{Y}(\theta) = Y(\tilde{\theta})$. Thus, the random variable $\bar{Y}(\theta)$ requires only a single evaluation of Y for each θ , which implies that the subgradient estimate in Equation 36 requires only two evaluations of Y . Note that the randomized extension has a mixture probability distribution given by

$$P\{\bar{Y}(\theta) \in A\} = \sum_{i=0}^d \lambda_i P\{Y(v_i) \in A\}, \quad (37)$$

where A is a measurable set of real numbers. It follows that

$$E[\bar{Y}(\theta)] = \bar{L}(\theta). \quad (38)$$

A variant of Refs. [48] and [50] is the DSPSA algorithm of Wang and Spall [54,55] and Wang [31]. The method of computing the difference estimates in Refs. [31,54,55] differ from those in Refs. [46–50] and applies to more general types of loss functions. Wang and Spall used “middle point” perturbations, where the observations Y of the loss function used to compute difference estimates are taken at $\lfloor \theta \rfloor + (\mathbf{1} \pm \Delta)/2$, and the term in the denominators are Δ_i^{-1} , rather than $2 \Delta_i^{-1}$. The notation $\mathbf{1}$ denotes the d -dimensional vector consisting of all 1's. Wang and Spall [54,55] and Wang [31] also examined the rate of convergence of their procedure. Wang [31] presents a detailed analysis of the convergence properties of the “middle point”

discrete SA procedure and compares its rate of convergence with the stochastic ruler and stochastic comparison methods.

Sample Path Methods

Sample path methods refer to a class of techniques that use sample average estimates of the loss function in the optimization (see, e.g., Refs. [43,56–60]). Thus, the estimates $\hat{\theta}_n$ are derived from a sample average estimate of the loss function, where the optimization is performed by optimizing $\hat{L}$. Thus, any applicable deterministic procedure can be used in the sample path approach.

There are two variants of sample path methods, depending on whether or not the sample path in the estimation is “fixed” or “variable.” To describe these estimates, let ω denote the random effects in the noise in (1). The observation corresponding to this value of ω is $Y(\theta, \omega)$. Let $\omega_1, \omega_2, \omega_3, \dots, \omega_m$ be an i.i.d. sample of ω , where $m \geq 1$ is fixed. This random sample defines a fixed sample path estimate of the loss

$$\hat{L}_m(\theta) = \frac{1}{m} \sum_{i=1}^m Y(\theta, \omega_i). \quad (39)$$

The sample of ω 's in this estimate of the loss function remain fixed throughout the estimation to obtain $\hat{\theta}_n$. A fixed sample path estimate of the loss yields a fixed sample path estimate of the optimum. This definition assumes that the parameter θ in $Y(\theta, \omega)$ can varied for a fixed value of ω . This is possible, in particular, when the observations Y are obtained by Monte Carlo.

Variable sample path estimates are obtained by letting the random effects vary with each sample of observations and iteration to obtain the estimate $\hat{\theta}_n$. In other words, consider a sample of k_n i.i.d. observations of $\omega_1^n, \omega_2^n, \omega_3^n, \dots, \omega_{k_n}^n$ of ω at each iteration n . These observation define a variable sample path estimate of the loss

$$\hat{L}_{k_n}(\theta) = \frac{1}{k_n} \sum_{i=1}^{k_n} Y(\theta, \omega_i^n). \quad (40)$$

The ω_i^j 's are assumed to be independent of the ω_i^l 's, for $j \neq l$. In addition, in the most general

form of (40), the sampling distribution for ω_i^n depends on the current estimate $\hat{\theta}_n$.

The key distinction between the two types of loss function estimates is that variable sample path estimates vary with iteration index for $\hat{\theta}_n$, whereas fixed sample path estimates do not.

The convergence of sample path methods has been extensively studied (see, e.g., Refs. [56–59]). Reference [59], for example, showed that the optimal value of $\hat{L}_m$, denoted $\hat{L}_m^*$, converges a.s. to the optimal value L^* of loss. It also studied approximate optimal solutions called δ -optimal solutions, $\delta \geq 0$. A point θ is a δ -optimal solution of L if $|L(\theta) - L^*| \leq \delta$. The loss function values of such points are within δ of the optimum L^* . The set of such points is denoted Θ_δ^* . When $\delta = 0$, the set of optimal and δ -optimal solutions coincide. Approximate optimal solutions of sample path estimates are similarly defined. Thus, a δ -optimal solution of $\hat{L}_m$ is any point θ such that $|\hat{L}_m(\theta) - \hat{L}_m^*| \leq \delta$. The set of such approximate optimal solutions is denoted $\Theta_{m,\delta}^*$. Convergence a.s. holds for approximate solutions ([59]): the set Θ_δ^* contains $\Theta_{m,\delta}^*$ a.s. for m sufficiently large.

The rates of convergence for sample path estimates are also known ([59]): for $\delta \geq 0$

$$\limsup_{m \rightarrow \infty} \frac{1}{m} \log [1 - P(\Theta_{m,\delta}^* \subset \Theta_\delta^*)] \leq -C. \quad (41)$$

In other words, the probability that Θ_δ^* contains $\Theta_{m,\delta}^*$ converges to 1 exponentially fast as $m \rightarrow \infty$. See Ref. [59] for performance bounds on sample path estimates. Reference [56] studied the convergence properties of variable sample path methods.

CONCLUSION

There are many approaches for discrete optimization. The particular choice depends on the problem structure, including the assumptions about the feasible region such as its cardinality, the measurement noise, and the loss function itself. For problems in which the feasible region is not large, statistical approaches are a reasonable choice, because those approaches require sampling the loss function at each point in the search space.

Random search methods and sample path methods are alternatives when the search space is large and there is little or no structure in the loss function that can be exploited in the optimization. For the random search methods, the modified stochastic ruler or modified SAN seem to be computationally efficient choices as they do not require an increasing number of function evaluations at each iteration. In situations where the search space is large and there are properties of the loss function that can be used in the search for an optimum, such as convexity, then stochastic approximation methods are available.

ACKNOWLEDGMENT

Sincere thanks are extended to the reviewers and the Topical Editor, Dr. James C. Spall. Their comments and suggestions for improving this manuscript were invaluable during the review process and were greatly appreciated.

DISCRETE-TIME MARTINGALES

KYLE Y. LIN

Operations Research Department,
Naval Postgraduate School,
Monterey, California

In the eighteenth century, martingales originally referred to a set of betting strategies that seemingly guarantees a sure win (pages 122–123 in Ref. 1). One such strategy is to instruct the gambler to wage \$1 on the first bet and to double up the wager after each loss, in the hope that he will eventually win a bet so as to win \$1 overall. For instance, if he loses three bets in a row, but wins the fourth bet, then he wins $-1 - 2 - 4 + 8 = \$1$.

In probability theory, a discrete-time martingale is a stochastic process designed to track a gambler's fortune in a sequence of fair bets. The concept of martingales came from Paul Pierre Levy, but it was Joseph Leo Doob (Ref. 2), who developed the theory. An important result of the martingale theory is that there exists no strategy that can guarantee a sure win in a fair game.

DEFINITION

In probability theory, a discrete-time martingale is a sequence of random variables that are motivated by a gambler's fortune in a fair game. Precisely, a discrete-time stochastic process $\{Z_n, n = 1, 2, \dots\}$ is called a *discrete-time martingale* if it satisfies the following two conditions:

$$E[|Z_n|] < \infty, \quad \text{for all } n, \quad (1)$$

and

$$E[Z_{n+1}|Z_1, Z_2, \dots, Z_n] = Z_n. \quad (2)$$

By interpreting Z_n as a gambler's fortune after the n th bet, Equation (2) states that the expected fortune after the $(n + 1)$ th bet is equal to the fortune after the n th bet, for

$n \geq 1$. In other words, the expected payoff of each bet is equal to 0, so the game is fair. The purpose of the technical condition in Equation (1), loosely speaking, is to ensure the mathematical regularity that allows the derivations of many useful results.

A discrete-time martingale tracks a gambler's fortune in a fair game. Taking expectations of Equation (2) results in

$$E[Z_{n+1}] = E[Z_n],$$

and therefore, $E[Z_n] = E[Z_1]$ for all n . An important result in martingale theory is that no strategy can guarantee a sure win in a fair game.

EXAMPLES

This section provides several examples of discrete-time martingales.

Example 1. Suppose that in each bet the gambler will win \$5, win \$2, or lose \$6, with respective probabilities 0.4, 0.2, and 0.4, independent of previous bets. Let Z_n denote the fortune after the n th bet, then $\{Z_n, n \geq 1\}$ is a discrete-time martingale, because

$$\begin{aligned} E[Z_{n+1}|Z_1, Z_2, \dots, Z_n] &= 0.4(Z_n + 5) \\ &+ 0.2(Z_n + 2) + 0.4(Z_n - 6) = Z_n. \end{aligned}$$

In fact, $\{Z_n, n \geq 1\}$ is a discrete-time martingale as long as the expected winning in each bet is \$0.

Although an arbitrary discrete-time stochastic process $\{X_n, n \geq 1\}$ is most likely not a discrete-time martingale, it is often possible to define another stochastic process $\{Z_n, n \geq 1\}$ based on $\{X_n, n \geq 1\}$, such that the new stochastic process is a discrete-time martingale.

Example 2. Let X_n denote the time of the n th arrival in a homogeneous Poisson process

with rate λ . The stochastic process $\{X_n, n \geq 1\}$ is not a discrete-time martingale because

$$E[X_{n+1}|X_1, \dots, X_n] = X_n + \frac{1}{\lambda} \neq X_n.$$

However, let $Z_n = X_n - n/\lambda$, then $\{Z_n, n \geq 1\}$ is a discrete-time martingale because

$$\begin{aligned} E[Z_{n+1}|Z_1, \dots, Z_n] \\ &= E\left[X_{n+1} - \frac{n+1}{\lambda} \middle| X_1, \dots, X_n\right] \\ &= \left(X_n + \frac{1}{\lambda}\right) - \frac{n+1}{\lambda} = X_n - \frac{n}{\lambda} = Z_n, \end{aligned}$$

where the first equality follows because $\{X_1, \dots, X_n\}$ can be deduced from $\{Z_1, \dots, Z_n\}$, so both of them provide the same information.

Example 3 [Likelihood Ratio Test].

Suppose we believe that a population is distributed either according to density function f or density function g . A random sample $X_1, \dots, X_n$ is taken and

$$Z_n = \prod_{i=1}^n \frac{g(X_i)}{f(X_i)}$$

is called the *likelihood ratio test statistic*. If the population is distributed according to density g , then the observations tend to occur at values where g is relatively large, so the test statistic tends to be large. For the same reason, if the population is distributed according to density f , then the test statistic tends to be small. The likelihood ratio test has important applications in statistical decision theory.

If the population is distributed according to density function f , then $\{Z_n, n \geq 1\}$ is a discrete-time martingale. To prove this claim, we compute

$$\begin{aligned} E[Z_{n+1}|Z_1, \dots, Z_n] \\ &= E\left[Z_n \frac{g(X_{n+1})}{f(X_{n+1})} \middle| Z_1, \dots, Z_n\right] \\ &= Z_n \times E\left[\frac{g(X_{n+1})}{f(X_{n+1})} \middle| Z_1, \dots, Z_n\right] \\ &= Z_n \times \int \frac{g(x)}{f(x)} f(x) \, dx = Z_n, \end{aligned}$$

where the third equality follows because X_{n+1} is independent of $X_1, \dots, X_n$, and therefore independent of $Z_1, \dots, Z_n$. The last equality follows because $g(x)$ is a density function, so $\int g(x) \, dx = 1$.

In the previous examples, it is quite straightforward to use Equation (2) directly to show that a stochastic process is a discrete-time martingale, but it is not always the case. Sometimes, it is more convenient to show that the conditional expected value of Z_{n+1} —given not only $Z_1, \dots, Z_n$, but also some additional information—is equal to Z_n (see page 296 in Ref. 3). If we can show that

$$E[Z_{n+1}|Z_1, \dots, Z_n, \mathbf{Y}] = Z_n,$$

then $\{Z_n, n \geq 1\}$ is a discrete-time martingale because

$$\begin{aligned} E[Z_{n+1}|Z_1, \dots, Z_n] \\ &= E[E[Z_{n+1}|Z_1, \dots, Z_n, \mathbf{Y}]|Z_1, \dots, Z_n] \\ &= E[Z_n|Z_1, \dots, Z_n] = Z_n, \end{aligned}$$

where the first equality follows from the identity

$$E[X|Z] = E[E[X|Y, Z]|Z]. \quad (3)$$

Example 4 [Doob Martingale]. When estimating the expected value of a random variable Y based on a sequence of observations $X_1, X_2, \dots$, we can write

$$Z_n = E[Y|X_1, X_2, \dots, X_n]$$

as the estimate after n observations. The sequence of estimates $Z_1, Z_2, \dots$ is a discrete-time martingale, and is named after Joseph Leo Doob. To show that $Z_1, Z_2, \dots$ is a discrete-time martingale, compute the conditional expected value of Z_{n+1} —given not only $Z_1, \dots, Z_n$, but also $X_1, \dots, X_n$ —as follows:

$$\begin{aligned} E[Z_{n+1}|Z_1, \dots, Z_n, X_1, \dots, X_n] \\ &= E[Z_{n+1}|X_1, \dots, X_n] \\ &= E[E[Y|X_1, \dots, X_n, X_{n+1}]|X_1, \dots, X_n] \\ &= E[Y|X_1, \dots, X_n] = Z_n, \end{aligned}$$

where the first equality follows because $Z_1, \dots, Z_n$ can be computed from $X_1, \dots, X_n$, and the third equality follows from Equation (3).

Perhaps two of the most important theorems concerning martingales are the martingale convergence theorem and the optional stopping theorem. Owing to its root in betting strategies, martingale theory has since found many applications in modern finance. Interested readers can refer to Refs 4 and 5 to see how martingale theory applies to financial modeling.

FURTHER READING

In this article, the discrete-time martingale is introduced without a rigorous mathematical definition based on measure theory. Readers can refer to Ref. 3 for a treatment with this approach.

A rigorous definition of discrete-time martingales relies on measure theory. Many textbooks on probability theory, such as Refs 2 and 6–9, introduce martingales with this approach. Reference 10 contains several interesting examples, where one can

cleverly devise a discrete-time martingale to derive elegant solutions for some interesting problems.

DISCRETIZATION METHODS FOR CONTINUOUS PROBABILITY DISTRIBUTIONS

ROBERT K. HAMMOND
J. ERIC BICKEL
The University of Texas, Texas,
USA

INTRODUCTION

Decision analysis problems typically involve probabilistic modeling of discrete and continuous uncertainties. Examples of discrete uncertainties include the presence of hydrocarbons and whether or not a competitor will enter the market. Examples of continuous uncertainties include the volume of hydrocarbons and market share. Discrete uncertainties are modeled with a probability mass function (pmf) and continuous uncertainties with a probability density function (pdf). In order to facilitate assessment or represent continuous uncertainties in a discrete decision tree, it is common for decision analysts to represent pdfs with properly designed pmfs, a process known as *discretization*.

Specifically, consider a decision model that takes as an input the continuous random variable X with support $S \subseteq \mathbb{R}$. We approximate the pdf $f(x)$, or the cumulative distribution function (cdf) $F(x)$, with a set of values $x_i \in S$, $i = 1, 2, \dots, N$, and associated probabilities $p_i \equiv p(x_i)$.

In most discretization methods, N is equal to three, but five is not uncommon. The values, which can be expressed as fractiles, or percentiles, of $F(x)$, and probabilities are selected such that desired properties of X are preserved. Common properties of interest are the moments of X (e.g., the mean, variance, skewness, and kurtosis). Smith [1] provided the following argument in support of matching moments: In decision and risk analysis, we are often interested in computing the expectation of some value function

(e.g., net present value or utility), $v(x)$, that is a function of the uncertain quantity X . If $v(x)$ can be closely approximated by a differentiable function, it can be written as a Taylor series expansion,

$$v(x) = v(a) + \frac{v'(a)}{1!}(x-a) + \frac{v''(a)}{2!}(x-a)^2 + \frac{v'''(a)}{3!}(x-a)^3 + \dots \quad (1)$$

Taking the expectation $E[v(X)]$ yields a weighted sum of the raw moments of X . For example, if $a = 0$, we have,

$$E[v(X)] = v(0) + \frac{v'(0)}{1!}E[X] + \frac{v''(0)}{2!}E[X^2] + \frac{v'''(0)}{3!}E[X^3] + \dots \quad (2)$$

Thus, a good approximation of $E[v(x)]$ must closely approximate the moments of X . In other words, in order to properly estimate the mean of our output variable, we need to match all the moments of the input variable.

Several discretization methods are in common use. For example, Extended Swanson–Megill (ESM) weights the 10th (P10), 50th (P50), and 90th (P90) percentiles of $F(x)$ by 0.300, 0.400, and 0.300, respectively. It is heavily used within the oil and gas industry [2–5], and has several other example applications in the literature [6–10]. A similar discretization is the “25-50-25” method, which weights the P10, P50, and P90 by 0.250, 0.500, and 0.250, respectively, and is also heavily used in the oil and gas industry [5]. Another method, Extended Pearson–Tukey (EPT), weights the P5, P50, and P95 by 0.185, 0.630, and 0.185. Example applications include Keeney [11] and Brooks and Kirkwood [12]. A flexible method called *bracket mean* (BMn), or equal areas, which uses the conditional means of partitions of a distribution is also commonly used [5]. Bickel et al. [5] and Hammond and Bickel [13] discussed the development and history of these and other methods.

The remainder of this article is organized as follows. The section titled “Discretization Methods” describes several discretization methods. The section “Example” gives example applications of some of these methods. The section “Multivariate Discretization” briefly discusses multivariate discretization, and the section “Discretization in Other Fields” gives an overview of discretization in other fields. The section “Recommendations for Practice” provides guidelines and recommendations for the practical application of these methods. Finally, the last section concludes.

DISCRETIZATION METHODS

Bickel et al. [5] categorized discretization methods into *shortcuts*, which do not require that the full distribution be known, and *distribution-specific*, which do. We first describe several shortcut methods, and then describe three distribution-specific methods.

Shortcuts

Shortcuts, as the name implies, are easy to apply and are a good starting point in probabilistic analysis. Many shortcuts have been proposed. Shortcuts are typically symmetric, that is, for a three-point discretization, $p_1 = p_3$ and $F^{-1}(x_1) = 1 - F^{-1}(x_3)$.

Table 1 summarizes several discretization shortcuts. Of these, EPT generally best preserves a distribution’s mean and variance, or the certain equivalent of a lottery when considering risk aversion [14, 15, 13]. ESM is generally best if the P10, P50, and P90 are used [13]. Although EPT is more accurate, ESM’s less extreme percentiles may be easier for experts to assess, making it more appropriate in some scenarios. MCS, though widely used, is generally inferior to ESM [16].

Hammond and Bickel [13] used the Pearson distribution system [17–19] to construct new three-point discretization shortcuts that are tailored to distributions with different ranges of support. The Pearson system subsumes many common distributions (e.g., normal, beta, uniform, and exponential) and is divided into several types. Three main types

make up the majority of Pearson distributions, the rest being special and limiting cases. These are the generalized beta (Type I), beta prime (Type VI), and the Type IV. The primary distinction between these three types are their ranges of support; the Type I has bounded support, $[a, b]$, the Type VI support is unbounded in one direction, $[a, \infty]$ or $[-\infty, b]$, and the Type IV has unbounded support, $[-\infty, \infty]$. Hammond and Bickel [13] found shortcuts that minimized the error in matching the mean, on average, over a large number of distributions in each of these types. This allows the analyst to tailor a shortcut to a distribution using only knowledge of the support boundedness. One set of shortcuts, the EPT++ methods,¹ were fit by changing the upper and lower discretization points and the probabilities, allowing them to be asymmetric. Another set, the standard percentile (SP) methods, fix the points to be the P10, P50, and P90, as these are commonly used in practice, and fit the probabilities. Table 2 gives the EPT++ shortcuts and Table 3 gives the SP shortcuts. Note that as the EPT++ shortcuts are asymmetric, and were fit to right-skewed distributions, the shortcuts should be reflected when dealing with left-skewed distributions. For example, the shortcut for a right-skewed type IV is (P7, P50, P94, 0.231, 0.551, 0.218), but for a left-skewed type IV, the shortcut would become (P6, P50, P93, 0.218, 0.551, 0.231). These shortcuts are more accurate than those in Table 1, on average, in matching the mean (and often the variance as well) of the distributions to which they were tailored.

Distribution-specific Methods

Distribution-specific methods require specifying the pdf (or the cdf) to be discretized, instead of only three percentiles. The first method we describe, Gaussian Quadrature (GQ), is a form of numerical integration designed to match the moments of a distribution. The other two methods, BMn,

¹The name indicates that these methods are an extension of the Pearson and Tukey [20] procedure. Hammond and Bickel [13] also found symmetric “EPT+” shortcuts.

Table 1. Summary of Shortcut Discretization Methods

Shortcut	Percentile Points	Probability Weights
Extended Pearson–Tukey (EPT)	P5, P50, P95	0.185, 0.630, 0.185
Extended Swanson–Megill (ESM)	P10, P50, P90	0.300, 0.400, 0.300
McNamee–Celona Shortcut (MCS)	P10, P50, P90	0.250, 0.500, 0.250
Zaino–D’Errico “Improved” (ZDI)	P4.2, P50, P95.8	0.167, 0.667, 0.167
Zaino–D’Errico–Tagichi (ZDT)	P11, P50, P89	0.333, 0.333, 0.333
Miller–Rice One-Step (MRO)	P8.5, P50, P91.5	0.248, 0.504, 0.248

Table 2. EPT++ Shortcuts

Distribution Type	Support	Percentile Points	Probability Weights
I-U Beta (EPT1U++)	$[a, b]$	P1, P50, P85	0.216, 0.491, 0.293
I-J Beta (EPT1J++)	$[a, b]$	P2, P50, P94	0.184, 0.615, 0.201
I- $\cap$ Beta (EPT1 $\cap$ ++)	$[a, b]$	P5, P50, P95	0.184, 0.632, 0.184
VI Beta Prime (EPT6++)	$[a, \infty]$	P4, P50, P96	0.164, 0.672, 0.164
IV (EPT4++)	$[-\infty, \infty]$	P7, P50, P94	0.231, 0.551, 0.218

Table 3. SP Shortcuts

Distribution Type	Support	Points	Probability Weights
I-U Beta (SP1U)	$[a, b]$	P10, P50, P90	0.228, 0.544, 0.228
I-J Beta (SP1J)	$[a, b]$	P10, P50, P90	0.273, 0.454, 0.273
I- $\cap$ Beta (SP1 $\cap$)	$[a, b]$	P10, P50, P90	0.296, 0.408, 0.296
VI Beta Prime (SP6)	$[a, \infty]$	P10, P50, P90	0.308, 0.384, 0.308
IV (SP4)	$[-\infty, \infty]$	P10, P50, P90	0.322, 0.356, 0.322

also known as *Equal Areas* [5], and bracket median (BMd), divide the cdf into intervals or brackets (three is common, but not necessary). BMn summarizes each interval with the conditional mean of that interval, whereas BMd uses the conditional median.

Gaussian Quadrature. GQ is a method of numerical integration that exactly matches the largest number of moments for any n -point discretization. Specifically, an n -point GQ will match the 0th through $2n-1$ st moments of the underlying distribution. Gauss [21] introduced the original method, which has been described more recently by Davis and Rabinowitz [22], among others. Miller and Rice [23] and Smith [1] described GQ applied to probability distributions for the purpose of discretization.

Smith [1] provided a procedure for finding an n -point GQ for a distribution F using

orthonormal polynomials.² First, construct the sequence of polynomials that are orthonormal with respect to F , $P_0^*, \dots, P_n^*$. These can be recursively computed:

$$\begin{aligned}
 P_{-1}(x) &= 0; P_0(x) = 1, \\
 P_{i+1}(x) &= (x - E[xP_i^{*2}(x)])P_i^*(x) \\
 &\quad - E[P_i^2(x)]^{1/2}P_{i-1}^*(x) \\
 &\text{for } 1 \leq i \leq n-1 \\
 &\text{where } P_i^*(x) = \frac{P_i(x)}{E[P_i^2(x)]^{1/2}}.
 \end{aligned}$$

E denotes the expectation with respect to F . The n roots of P_n^* , $y_1, \dots, y_n$, are distinct

²Miller and Rice [23] alternatively constructed a linear system of equations to solve for the polynomial coefficients.

and provide the n discretization values. The corresponding probabilities are given by,

$$p_i = \frac{k_n}{k_{n-1}P_n^*(y_i)P_{n-1}^*(y_i)},$$

where k_n and k_{n-1} are the leading coefficients of $P_n^*(x)$ and $P_{n-1}^*(x)$, and $P_n^*(x)$ denotes the derivative of $P_n^*(x)$. See Smith [1, 24] for more thorough discussion and proofs.

While GQ is the most accurate in terms of moment matching, it is also the most complex method to apply. GQs for some common distributions have been tabulated [5], but finding a GQ in general requires software implementation to find the roots y_i .

GQ typically uses rather extreme values (e.g., the P99.9) for some discretization points, in order to match higher moments. A criticism of this method is that expert assessments or historical data are often unreliable for such extreme values. We can address this issue by a modification that in turn reduces the number of moments that can be matched. Rather than taking the n roots of P_n^* as the discretization values, we can specify the values *a priori*, for example, using a set of percentiles. The probabilities matching the 0th through $n-1$ st moments can then be found by solving the linear equations,

$$\sum_{i=1}^n p_i x_i^j = \mu_j, \quad j = 0, \dots, n-1$$

$$p_i \geq 0, i = 1, \dots, n$$

for the p_i , where the x_i 's are given, μ_j is the j th raw moment, and $j = 0$ is the condition that the probabilities sum to one. However, this system is not guaranteed to have a solution for all sets of values x_i . Bickel et al. [5] demonstrated this method using the P10, P50, and P90 for uniform, normal, exponential, and triangular distributions.

Bracket Mean. BMn partitions the distribution support into intervals or brackets and then uses the conditional means of these regions. The method is more adaptable to the underlying distribution than the shortcuts and is also easier to apply than GQ. BMn

perfectly matches the mean of the underlying distribution, but always underestimates the variance and higher even-moments [23]. Hammond and Bickel [13] demonstrated that BMn's error in the variance, for three- and five-point bracket examples, tends to be higher than some three-point discretization shortcuts, such as EPT.

Part of BMn's appeal stems from the fact that it can be graphically explained and applied to a distribution for which the cdf, but not necessarily the functional form, is available [25]. For example, Fig. 1 shows the cdf of a standard-normal distribution. Divide the cumulative scale into three intervals: [0.0, 0.25], [0.25, 0.75], and [0.75, 1.0] (this division is common but arbitrary). To find the conditional mean of the first bracket, which we will use as the discretization point x_1 , find the location of the vertical line that makes the shaded areas A_1 and A_2 equal. The X value at this point is conditional mean. For a proof of this method, see Merkhofer [25] or McNamee and Celona [26]. Repeat for each interval, assigning the probability of an interval to the corresponding point as the discretization. Here, the points -1.24 , 0 , and 1.24 are respectively assigned probabilities 0.25 , 0.50 , and 0.25 .

Bracket Median. BMd uses the conditional *medians* of the partitions of the support. If partitioning on the cumulative probability axis, the medians can be determined simply by finding the appropriate percentiles. In that case, the median is just the percentile midway between the ends of a bracket (i.e., for the bracket [0, 0.25], the median is the 0.125 percentile, or the P12.5). As the conditional distributions are generally skewed, the median and the mean differ and BMd will regularly result in different discretizations than BMn.

Despite BMd's simple application, it typically incurs large errors in the moments. Hammond and Bickel [13] showed that three- and five-point BMd discretizations using equal-sized brackets tend to perform far worse than three- and five-point BMn, and even the less-accurate shortcuts, in matching the mean and variance of a distribution.

Figure 1. Example application of bracket mean with intervals $[0, 0.25]$, $[0.25, 0.75]$, $[0.75, 1]$.

Table 4. SP6 Values and Probabilities for Lognormal(1, 0.5)

Values	1.4322	2.7183	5.1592
Probabilities	0.3080	0.3840	0.3080
Percentiles (%)	10.00	50.00	90.00

Table 5. SP6 Moment Errors for Lognormal(1, 0.5)

	Mean	Variance	Skewness	Kurtosis
Est. Moments	3.0740	2.2180	0.4276	1.6398
% Error	-0.20%	-17.69%	-75.57%	-81.57%

However, BMd is frequently recommended in decision analysis texts [27–29].

EXAMPLE

In this section, we illustrate the use of SP, EPT++, GQ, and BMn on a lognormal distribution with parameters $\mu = 1$, $\sigma = 0.5$.

SP6

Our first example will demonstrate one of the SP shortcuts. Because the lognormal distribution is unbounded to only one side, we use

the SP6 shortcut. The lognormal cdf and the resulting SP6 discretization cdf are shown in Fig. 2. The values and probabilities used by the discretization are given in Table 4. The SP6 shortcut is similar to ESM, but assigns slightly higher probabilities to the P10 and P90. The SP6 moment estimations and errors for the mean, variance, skewness, and kurtosis of this lognormal distribution are given in Table 5. Note the high errors in the skewness and kurtosis estimations of -75.57% and -81.57% , respectively.

Figure 2. SP6 cdf.

Table 6. EPT6++ Values and Probabilities for Lognormal(1, 0.5)

Values	1.1328	2.7183	6.5231
Probabilities	0.1640	0.6720	0.1640
Percentiles (%)	4.00	50.00	96.00

EPT6++

Now we demonstrate one of the EPT++ shortcuts. Because the lognormal distribution is unbounded to only one side, we use the EPT6++ shortcut. The lognormal cdf and resulting discretization cdf are shown in Fig. 3. The values and probabilities for the discretization are given in Table 6. This shortcut closely matches the mean and variance, with errors of 0.07% and -1.52% , respectively, but significantly underestimates the skewness and kurtosis, with errors of -28.20% and -59.52% , respectively, as seen in Table 7. This poor performance in matching the skewness and kurtosis, also seen in Table 5 for SP6, is typical of shortcut methods, especially for unbounded distributions. The distribution tails, which shortcuts do not capture well, are more important to these higher moments than to the mean and variance. Again comparing Tables 5 and 7, we see that EPT6++ has lower errors in each of the first four moments than SP6, as its more extreme percentiles better capture the tails than SP6. However, EPT6++'s more extreme percentiles may be

more difficult to assess than the P10 and P90 used by SP6.

GQ

Here, we demonstrate three- and five-point GQs, GQ3, and GQ5, respectively. GQ3 matches moments 0 through 5 and GQ5 matches moments 0 through 9, so we do not give moment errors.³ The cdfs are shown in Fig. 4, and the values, probabilities, and equivalent percentiles are given for GQ3 and GQ5 in Tables 8 and 9, respectively. Notice the extreme percentiles used by each method, both making use of the P99.9, or more extreme, percentiles.

The set of orthonormal polynomials for GQ3 in this example are

$$P_{-1}^*(x) = 0$$

$$P_0^*(x) = 1$$

$$P_1^*(x) = -1.876 + 0.609x$$

$$P_2^*(x) = 2.640 - 1.524x + 0.169x^2$$

$$P_3^*(x) = -3.207 + 2.484x - 0.489x^2 + 0.024x^3$$

³Since GQ requires numeric computation, there will generally be negligible numerical errors.

Table 7. EPT6++ Moment Errors for Lognormal(1, 0.5)

	Mean	Variance	Skewness	Kurtosis
Est. Moments	3.0822	2.6539	1.2567	3.6017
% Error	0.07%	-1.52%	-28.20%	-59.52%

Figure 4. GQ3 and GQ5 cdfs.

BMn

Figure 5 shows the cdfs for a three-point bracket mean discretization (BMn3) using the brackets $[0, 0.25]$, $[0.25, 0.75]$, and $[0.75, 1]$ (alternatively referred to as 25-50-25) and a five-point bracket mean discretization (BMn5) using equal brackets of 0.2. The values and probabilities for BMn3 and BMn5 are given in Tables 10 and 11, respectively.

While any BMn discretization will theoretically match the mean of the distribution, they are often inferior to some shortcuts in matching higher moments. The moment errors for BMn3 and BMn5 in Tables 12 and 13, respectively, are larger than those for EPT6++ in the variance, skewness, and kurtosis, as seen by comparing these to Table 7.

The discretization points are more tightly clustered about the mode of the distribution

than GQ, which, like the shortcuts, fails to capture the distribution tails. Whether BMn or a shortcut is preferred depends on the importance of the different moments.

MULTIVARIATE DISCRETIZATION

Here, we briefly discuss multivariate discretization. Much of the arguments for, and analysis of, univariate discretization methods does not extend to multiple variables. For example, there is no “mean” of a multivariate distribution $f(X_1, \dots, X_N)$ with support S^N without specification of a function $v(x_1, \dots, x_N): S^N \rightarrow \mathbb{R}$.

Keefer and Bodily [14] discussed sequential discretization of multivariate distributions. If we wish to discretize $f(X, Y)$, first discretize X , then discretize the conditional distribution $Y|x_i$. Some examples make use of sequential discretization of individual variables of a multivariate model with dependent components. Clemen and Reilly [30] and Wang and Dyer [31] used copulas to model multivariate distributions, and discretized the resulting conditional distributions.

Alternatively, the uncertainties of a multivariate distribution may be simultaneously discretized. Hoyland and Wallace [32] fit a discretization to multiple uncertainties by solving a (generally nonconvex) optimization problem of minimizing a distance measure of the differences in statistical properties of the continuous and discrete joint distributions. This optimization problem generally does not guarantee an optimal solution, and like GQ, requires software implementation.

DISCRETIZATION IN OTHER FIELDS

Discretization has wide application in fields other than decision analysis. Some of these have different aims than decision analytic discretization, such as summarizing or

partitioning data rather than approximating a continuous probability distribution.

Data Mining and Machine Learning

The data mining and machine learning fields are concerned with classification problems and often discretize real-valued observational data. Kotsiantis and Kanellopoulos [33] reviewed the literature on discretization for machine learning applications. They discussed variations of bracket methods for summarizing and categorizing data statically (considering one uncertainty at a time) and dynamically (considering multiple uncertainties simultaneously to incorporate dependence). Mizianty et al. [34] gave a wealth of references for discretization in classification problems, and compare the performance of 12 Naïve Bayes discretization algorithms.

Stochastic Programming

Multistage stochastic programming is another field that often requires distribution approximations to make the problems tractable. Kaut and Wallace [35] reviewed several methods used in the stochastic programming literature, including moment matching using GQ. Kall et al. [36] discussed discretization using partitions of the distributions’ support (bracket methods), particularly a method corresponding to BMn, which can be used with the Jensen and Edmundson–Madansky inequalities to bound the optimal value [37]. Other methods include Monte Carlo sampling [38] and nonlinear optimization [39, 40]. Discretization is also sometimes called *scenario generation*, as the result is a discrete set of uncertainty realizations.

Histograms

Histograms are commonly used to graphically represent frequency data and are discrete by definition. Histograms represent the frequencies or counts of observations falling

within a particular range (also known as a *bin*) as the height of the bar in the graph. The discretization methods discussed in this article are typically used as simplifying approximations to continuous distributions, whereas histograms are used to represent the distributions implied by empirical data [41]. The parameters for constructing a histogram include the number of bins, bin widths, and orientation of the bins. Two common heuristic rules for selecting the parameters for histograms with homogenous bin widths are Sturges' Rule, which determines the number of bins, and Scott's Rule, which determines the bin width for a given number of bins [41, 42, 43]. The flexibility of histogram derivation rules are limited by the quality and format of the empirical data, such as when the data are collected into bins of unequal width [44].

PERT

The Program Evaluation and Review Technique (PERT) is a popular method for estimating project completion time that began as a US Navy project to develop a quantitative evaluation methodology for project management [45]. PERT methods typically use separate estimation formulae for the mean and variance that don't necessarily form discrete probability distributions. The classical PERT formula for estimating the mean and variance use weighted combinations of the P0, mode, and P100 [46]. Many variations of these formulae have been proposed [47–55].

Finance

Discretization is often used in financial asset pricing models, such as the well-known binomial lattice model [56]. Moment-matching is common, and examples include Tauchen and Hussey [57], who used GQ in asset pricing with dynamic nonlinear models, and Sullivan [58] who used it to value American put options.

RECOMMENDATIONS FOR PRACTICE

Shortcut methods are useful as first approximations, which can be used in sensitivity

analysis to help identify important uncertainties. These uncertainties can then be given more attention when ascertaining the full distribution and using discretization methods such as GQ or BMn with several points. The discretizations should evolve with the analysis and be adapted to the importance of specific uncertainties. The characteristics of the decision ultimately determine the appropriateness of model refinement.

The choice of discretization method generally depends on two factors: the information available and the significance of the uncertainty to the decision(s). GQ is a highly accurate method that matches several moments of the distribution, but requires that these moments exist and be known. It can also be difficult to implement, and as a result might be best reserved for approximating key uncertainties. GQs have been tabulated for some common distribution families (e.g., normal, uniform, and triangular), but use of the method generally requires software [5].

If the full distribution is known, but GQ is not feasible or not desired, there are many potential methods to choose from. BMn, BMd, and GQ all give the analyst the freedom to choose the number of points, and in the case of BMn and BMd, the intervals to use. BMn is generally more accurate than BMd in matching moments using a given number of discrete points and specified intervals. For multi-modal distributions, BMn is far more accurate than shortcut methods, which can be very poor at approximating these distributions [13]. BMd is the simplest of these to automate, as it requires only reading percentiles from the continuous distribution, and may be preferred if calculation time is a concern.

It is often the case in decision analytic applications that probability assessments are expensive or time-consuming, such as resulting from the output of a large simulation model or as the result of careful expert judgment. In these cases, it may only be feasible to assess a few percentiles of the distribution, in which case discretization shortcuts are most valuable. EPT and ZDI are generally good choices, but better performance might be obtained using the EPT+ and

EPT++ shortcuts for their respective distribution types. If the distribution is bounded on both ends, then the analyst might be able to use knowledge of its shape (e.g., whether it is $\cap$ -shaped) to further specify the appropriate approximation. If the analyst is constrained to use the common P10, P50, and P90 percentiles, then choosing one of the SP methods provides distinct improvements over ESM or MCS. However, it should be remembered that shortcuts can incur large errors for even moderately skewed distributions. Shortcuts using more extreme percentiles (e.g., P5 and P95) tend to be more accurate for skewed distributions, but still incur errors. As mentioned above, shortcuts are particularly useful as first approximations in sensitivity analysis, to determine which uncertainties are most important and warrant more careful assessment and discretization.

SUMMARY

We have described the use of several different methods of discretizing continuous probability distributions, each having its own advantages and drawbacks. GQ is the best in terms of matching the moments of a distribution, but is not trivial to apply in practice without software support, and often uses extreme discretization values. Shortcuts, however, are generally tailored *a priori* to a wide range of distributions, and while they usually have some error (which can be large), they are very easy to apply. BMn is a compromise between the two approaches, being relatively easy to apply and reliably matching the mean. However, it does not match higher moments well.

Which method is most appropriate ultimately depends on the situation. Uncertainties to which a decision is very sensitive should be more accurately assessed and discretized during the analysis. Shortcuts are useful for first approximations of distributions used in initial probabilistic analysis. The iterative nature of the decision analysis cycle [59] should be used to refine the discretizations of those uncertainties that are most important, as a part of sensitivity analysis and information gathering.

INTRODUCTION

A general optimization problem can be expressed in the form

$$\min \{cx : x \in S\}, \quad (1)$$

where $x \in \mathbb{R}^n$ is the vector of decision variables, $c \in \mathbb{R}^n$ is a linear objective function, and $S \subset \mathbb{R}^n$ is the set of feasible solutions of Equation (1). Because S is generally hard to deal with, a possible approach for tackling Equation (1) is to optimize the objective function over a suitable relaxation (i.e., easy to solve) $P \supseteq S$. Let x^* be the optimal solution over P . If $x^* \in S$ the problem is solved. Otherwise, one can derive a valid inequality for S in order to separate x^* from S , that is, an inequality $\alpha x \geq \beta$ satisfied by all the feasible solutions in S and such that $\alpha x^* < \beta$. The addition of the cutting plane $\alpha x \geq \beta$ to the constraints defining P leads to a tighter relaxation $P' = P \cap \{x \in \mathbb{R}^n : \alpha x \geq \beta\}$ and the process can eventually be iterated.

The disjunctive approach to the separation problem, as introduced by Balas [1], considers defining an intermediate set $Q \supseteq S$ not containing x^* and separating x^* from Q . The set Q is obtained by applying to P a valid disjunction D for the set S , such as

$$D := \left\{ x \in \mathbb{R}^n : \bigvee_{h=1}^q D^h x \geq d_0^h \right\}, \quad (2)$$

where $D^h \in \mathbb{R}^{m_h \times n}$, $d_0^h \in \mathbb{R}^{m_h}$ ($h = 1, \dots, q$), and $S \subseteq D$ (i.e., any feasible solution of Equation (1) satisfies at least one of the conditions of D). Thus, the set Q , denoted as the *disjunctive hull* of D , is defined as $Q := \text{conv}(P \cap D)$, and any valid inequality for Q is a disjunctive cutting plane for problem (1). An alternative approach consists in solving all the problems

$$\min \{cx : x \in S, D^h x \geq d_0^h\}, \quad h = 1, \dots, q, \quad (3)$$

as at least one of these yields the optimal solution to Equation (1). In this case, Equation (1) is solved by *branching* instead of *cutting*.

Since the early 1990s, the disjunctive approach has been successfully exploited both in the context of mixed integer linear programs (MILPs) as well as in that of mixed integer nonlinear programs (MINLPs). The article titled **Disjunctive Programming** gives a general overview of disjunctive programming. In the present entry we survey some applications and extensions of disjunctive programming with special emphasis on recent developments. The paper is organized as follows: In the next section we recall the basic ingredients of disjunctive inequalities for MILPs and we report on recent results on this topic. In the section titled “Disjunctive Inequalities in MINLP,” the application of disjunctive constraints both as modeling tools and cutting planes is discussed for MINLPs. Finally, in the section titled “Branching on General Disjunctions,” we

consider the application of disjunctions as branching conditions in enumerative algorithms, as opposed to the cutting approach.

DISJUNCTIVE INEQUALITIES IN MILP

In the special case of an MILP, S is defined as $S = \{x \in \mathbb{R}^n : Ax \geq b, x \geq 0, x_i \in \mathbb{Z} \forall i \in N^I\}$, where $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$, and $N^I \subseteq \{1, \dots, n\}$ is the set of variables constrained to be integers. In this context, the intrinsic difficulty of the problem is due to the integrality restrictions on the variables in N^I . Thus, the relaxation P that is typically considered is the polyhedron associated with S , that is, $P = \{x \in \mathbb{R}^n : Ax \geq b, x \geq 0\}$. Because

$$\begin{aligned} P \cap D &= P \cap \{x \in \mathbb{R}^n : \bigvee_{h=1}^q D^h x \geq d_0^h\} \\ &= \bigcup_{h=1}^q \left(P \cap \{x \in \mathbb{R}^n : D^h x \geq d_0^h\} \right), \end{aligned}$$

then the disjunctive hull Q (for a fixed disjunction D) is defined as a union of polyhedra. More precisely,

$$Q := \text{conv} \left(\bigcup_{h=1}^q P_h \right),$$

with $P_h := P \cap \{x \in \mathbb{R}^n : D^h x \geq d_0^h\}$. In such a case, Balas [1,2] has shown that Q is a polyhedron as well. Even if a full description of Q in the space of the x variables may require an exponential number of constraints, the key result of Balas [1,2] is that Q has a compact representation in a higher-dimensional space. Namely, there exists a polyhedron $\tilde{Q} := \{(x, y) \in \mathbb{R}^{n+p} : Bx + Cy \geq d\}$ whose projection onto the x -space is Q , and $\tilde{Q}$ has $O(qn)$ variables and $O(qm + \sum_{h=1}^q m_h)$ constraints. This implies that separating x^* from Q can be solved by linear programming.

Indeed, each polyhedron P_h ($h = 1, \dots, q$) can be defined as $P_h = \{x \in \mathbb{R}^n : A^h x \geq b^h, x \geq 0\}$, where

$$A^h = \begin{bmatrix} A \\ D^h \end{bmatrix} \text{ and } b^h = \begin{bmatrix} b \\ d_0^h \end{bmatrix}.$$

Another key result of Balas [2] is that all the inequalities $\alpha x \geq \beta$ valid for Q are described by the polyhedral cone

$$\begin{aligned} Q^\# &= \left\{ (\alpha, \beta) \in \mathbb{R}^{n+1} : \alpha \geq u^h A^h, \beta \leq u^h b^h \right. \\ &\quad \left. \text{for some } u^h \geq 0, h = 1, \dots, q \right\}. \end{aligned}$$

Furthermore, for a full-dimensional polyhedron Q there is a one-to-one correspondence among the extreme rays of $Q^\#$ and the facets of Q .

Separating Disjunctive Cuts in MILP

Typically, disjunctive cuts are separated by considering a very special subset of two-term disjunctions (i.e., with $q = 2$), namely, the so-called split disjunctions of the form of Equation

$$\pi x \leq \pi_0 \quad \bigvee \quad \pi x \geq \pi_0 + 1, \quad (4)$$

with $\pi \in \mathbb{Z}^n$, $\pi_0 \in \mathbb{Z}$, $\pi_i = 0 \forall i \notin N^I$. Disjunctive cuts arising from disjunctions of the form (4) are also known as *split cuts* [3] (see **Split Cuts**).

Given a solution x^* of $P \setminus S$, a common approach for separating x^* from S is to consider an *elementary* split disjunction of the form

$$x_i \leq \pi_0 \quad \bigvee \quad x_i \geq \pi_0 + 1, \quad (5)$$

where $x_i \in N^I$, $x_i^* \notin \mathbb{Z}$, $\pi = e_i$ is the i -th unit vector, and $\pi_0 = \lfloor x_i^* \rfloor$. Thus, the disjunctive hull Q is simply defined as the union of the two polyhedra $P_0 = \{x \in P : x_i \leq \pi_0\}$ and $P_1 = \{x \in P : x_i \geq \pi_0 + 1\}$. By Farkas lemma, a most-violated disjunctive cut $\alpha x \geq \beta$ valid for Q , with $(\alpha, \beta) \in Q^\#$, can be found by solving the so-called *cut-generating linear program* (CGLP) that determines the Farkas multipliers (u, u_0, v, v_0) associated with the inequalities defining P_0 and P_1 so as to maximize

¹For 0–1 mixed integer programs, split cuts arising from elementary disjunctions of the form (7) are denoted as *lift-and-project* cuts [4] (see **Lift-and-Project Inequalities**).

the violation of the resulting cut with respect to x^* :

$$\begin{aligned}
 (\text{CGLP}) \quad & \min \quad \alpha x^* - \beta \\
 & \alpha \geq uA - u_0 e_i, \quad \beta \leq ub - u_0 \pi_0, \\
 & \alpha \geq vA + v_0 e_i, \quad \beta \leq vb + v_0(\pi_0 + 1), \\
 & u, v, u_0, v_0 \geq 0.
 \end{aligned} \tag{6}$$

Once a violated cut has been found as a solution of Equation (6), the cut can be easily strengthened *a posteriori* through the Balas and Jeroslow [5] procedure. Such a strengthening can be seen as finding the best split disjunction for a given set of Farkas multipliers, that is, the split disjunction that yields the strongest possible disjunctive cut over the nonnegative orthant $\{x \in \mathbb{R}_+^n\}$.

By construction, any feasible CGLP solution with negative objective function value corresponds to a violated disjunctive cut. However, the feasible CGLP set is a cone and needs to be truncated by means of a suitable normalization condition, so as to produce a bounded linear program (LP) in case a violated cut exists. Different normalization conditions might lead to completely different results in terms of the *strength* of the separated cuts because they heavily affect the choice of the optimal CGLP solution.

Several normalizations have been proposed in the literature, see, e.g., Balas *et al.* [4,6], Ceria and Soares [7], Balas and Perregaard [8], and Fischetti *et al.* [9]. The most natural and simple normalization is

$$u_0 + v_0 = 1, \tag{7}$$

and takes into account only the dual multipliers of the disjunctive constraints. Such a normalization has been considered, for instance, by Balas and Saxena [10] to optimize over the first *split closure*, that is, the polyhedron obtained by adding to P all split cuts which could be derived from the original set of linear constraints (see **Basic Polyhedral Theory** and **Split Cuts**). One of the most widely used (and effective) truncation conditions reads instead

$$eu + ev + u_0 + v_0 = 1, \tag{8}$$

where $e = (1, \dots, 1)$. This latter condition was proposed by Balas [11] and investigated, for instance, by Ceria and Soares [7] and Balas and Perregaard [8,12].

Recently, Fischetti *et al.* [9] analyzed computationally the above two normalization conditions, thus showing that the truncation condition (8) generally outperforms condition (7). Indeed, normalization in Equation (8) naturally enforces the separation of *sparse* and *low rank* inequalities that turn out to be more effective in terms of the percentage of the integrality gap closed.

Unfortunately, any normalization can in some cases produce weak cuts. The projection of the disjunctive cone of Equation (6) onto the polar space (α, β) yields precisely the cone $Q^\#$. As discussed, for a full-dimensional polyhedron Q , there is a one-to-one correspondence among the extreme rays of $Q^\#$ and the facets of Q . However, this correspondence is lost in the cone of Equation (6), that is defined in a lifted space that explicitly involves the Farkas multipliers (u, v, u_0, v_0) . Indeed, there are many extreme rays of the CGLP cone that correspond to dominated cuts, and this property is independent of the normalization used to truncate the cone. Fischetti *et al.* [9] gave a theoretical characterization of *weak rays* of the disjunctive cone of Equation (6) that lead to dominated cuts, and showed how the presence of redundant constraints in the formulation of P_0 and P_1 increases the number of weak rays in Equation (6), thus affecting the quality of the generated disjunctive cuts. It remains an open question how to find a computationally efficient way of dealing with redundant constraints in the separation.

A key step in the separation of disjunctive cuts for MILPs is the work by Balas and Perregaard [12]. Even if disjunctive cuts can be separated by linear programming, solving the CGLP in the lifted space (u, v, u_0, v_0) may be in general, too time consuming. Addressing the normalization of Equation (8), Balas and Perregaard [12] provided a precise correspondence between the bases of the CGLP truncated with Equation (8) and the bases of the original LP $Ax - Is = b, x \geq 0, s \geq 0$. Then, they developed an elegant and efficient way of solving the CGLP by performing pivot

operations in the original tableau involving (x, s) variables only.

In particular, Balas and Perregaard [12] also showed that the *mixed integer gomory* (MIG) cut [13] associated with the row of the basic variable x_i , $i \in N^I$, in the optimal simplex table of the system $Ax - Is = b, x \geq 0, s \geq 0$, corresponds to a basic solution of the CGLP truncated with Equation (8). Thus, solving the CGLP with normalization of Equation (8) can be interpreted as a way of strengthening the MIG cut from the table. Indeed, the basic CGLP solution yielding the MIG cut is precisely an *optimal* solution if the CGLP is truncated with the normalization of Equation (7) [4,8,9,12]. Hence, the strengthening of the MIG cut lies in the better behavior of the normalization of Equation (8) with respect to Equation (7).

The work by Balas and Perregaard [12] has been recently extended by Balas and Bonami [14]. In Ref. 14, the authors considered different normalization conditions of the form

$$\lambda u + \lambda v + u_0 + v_0 = \lambda_0,$$

with $\lambda \in \mathbb{R}_+^m$, $\lambda_0 \in \mathbb{R}_+$, and developed a procedure that iteratively combines the “pivoting mechanism” of Ref. 12 for finding the best set of Farkas multipliers for a fixed disjunction, with the Balas and Jeroslow [5] strengthening of the disjunction for a given set of multipliers. The results presented in Ref. 14 show that disjunctive inequalities can be profitably used to improve on the performance of general purpose branch-and-cut algorithms.

DISJUNCTIVE INEQUALITIES IN MINLP

Disjunctions are essential for modeling several types of nonconvex constraints, including those arising in MINLP. For these problems, S is defined as

$$S = \left\{ x \in \mathbb{R}^n : g_j(x) \leq 0 \ \forall j \in M, x_i \in \mathbb{Z} \ \forall i \in N^I \right\},$$

where, for all $j \in M$, $g_j : \mathbb{R}^n \rightarrow \mathbb{R}$ is a multivariate (possibly nonconvex) function. When all of the g_j are affine, we have an MILP, which is therefore a subclass of MINLP.

While the integrality of a subset of variables represents an important class of nonconvex constraints, there exist other nonconvexities in MINLP that can give rise to disjunctions, and that can be used by branch-and-bound algorithms. Below, we describe a few examples of how disjunctions are used to generate disjunctive inequalities for the general MINLP case and for some special cases.

General Nonconvex MINLP

Despite the more general nonlinear setting, most of the literature in MINLP and global optimization consider linear disjunctions of the form (2). MINLP solvers address nonconvex nonlinear constraints by means, for example, of *spatial* disjunctions, which are of the form $x_i \leq \pi_0 \vee x_i \geq \pi_0$.

One of the lower bounding procedures for nonconvex MINLP consists of *reformulating* the set of constraints into a set of nonconvex equality constraints of the form $x_k = f_k(x_1, x_2, \dots, x_{k-1})$, with $f_k : \mathbb{R}^{k-1} \rightarrow \mathbb{R}$ nonlinear [15,16]. A lower bound can then be obtained by solving an LP relaxation of the reformulation, with $\bar{n} \geq n$ variables: $P_{LP} = \{x \in \mathbb{R}^{\bar{n}} : Ax \geq b\}$. P_{LP} is constructed by adding, for each constraint $x_k = f_k(x_1, x_2, \dots, x_{k-1})$, a system of linear constraints $A^k x \geq b^k$ which constitutes a relaxation of the set $\{x \in \mathbb{R}^k : x_k = f_k(x_1, x_2, \dots, x_{k-1})\}$. An example of this step is shown in Fig. 1(a) for the constraint $x_2 = f_2(x_1) = x_1^2$, where the inequalities of $A^k x \geq b^k$ delimit the shaded area.

Let x^* be the optimal solution to P_{LP} . If x^* satisfies integrality constraints and all nonlinear constraints $x_k = f_k(x_1, x_2, \dots, x_{k-1})$, the problem is solved. If it satisfies all integrality constraints while violating at least one of the nonlinear ones, a disjunction is sought that is violated by x^* . The simple disjunction $x_i \leq \pi_0 \vee x_i \geq \pi_0$, although valid for MINLP, is clearly not violated. However, the linear relaxations P'_{LP} and P''_{LP} of $S' = S \cap \{x \in \mathbb{R}^n : x_i \leq \pi_0\}$ and $S'' = S \cap \{x \in \mathbb{R}^n : x_i \geq \pi_0\}$, respectively, depicted in Fig. 1(b), contain new linear constraints that can be used to construct a disjunction of type (2) that is violated by x^* .

Figure 1. An MINLP disjunction. In (a) an LP relaxation of a nonconvex constraint, the shaded area is the LP relaxation of the constraint $x_2 = f_2(x_1) = (x_1)^2$ with $x_1 \in [\ell_1, u_1]$, whereas (x_1^*, x_2^*) is the value of x_1 and x_2 in the optimum of the LP relaxation. In (b) a simple MINLP disjunction, a disjunction $x_1 \leq \pi_0 \vee x_1 \geq \pi_0$, albeit not violated by (x_1^*, x_2^*) , can be used to generate two LP relaxations (the two smaller shaded areas) which in turn allow to construct a disjunction $D^1x \geq d^1 \vee D^2x \geq d^2$ violated by x^* .

Since a disjunctive inequality for $P'_{LP} \cup P''_{LP}$ is also valid for $S' \cup S''$, a procedure similar to that used in MILP, where the CGLP is solved using the LP relaxation, can be applied [17]. Zhu *et al.* [18] proposed a simple extension to MINLP where the CGLP is solved for disjunctions on binary variables.

Special Classes of MINLP

Specific cutting-plane procedures can be devised for MINLPs with a certain structure. For MINLP with binary variables and whose continuous relaxation is convex, Stubbs and Mehrotra [19] generalized the procedure proposed by Balas *et al.* [4] and described a separation procedure based on a convex optimization problem.

A similar (specialized) procedure has been successfully applied to mixed integer conic programming (MICEP) problems, which can be thought of as MILP amended by a set of conic constraints. The second-order cone and the cone of symmetric semidefinite matrices are among the most important classes of conic constraints in this class. Çezik and Iyengar [20] and later Drewes [21] proposed, for MICEP where all disjunctions are generated from binary variables, an application of the separation procedure for disjunctive cuts to the conic case, whereby inequalities are

obtained by solving a continuous conic optimization problem. Analogously, Frangioni and Gentile [22] describe a special case of disjunctive inequalities called *perspective cuts*. These are obtained from the perspective relaxation of a convex MINLP containing binary variables used to model semicontinuous variables, as discussed by Aktürk *et al.* [23] and Linderoth and Günlük [24].

Mathematical Programs with Equilibrium Constraints (MPEC). These MINLPs contain nonconvex constraints $x^\top y = 0$, with $x \in \mathbb{R}_+^k$, $y \in \mathbb{R}_+^k$. These can be more easily stated as $x_i y_i = 0$ for all $i = 1, 2, \dots, k$, and give rise to simple disjunctions $x_i = 0 \vee y_i = 0$. Júdice *et al.* [25] studied mathematical programming with equilibrium constraints (MPEC) where the only nonlinear constraints are the complementarity constraints. Relaxing the latter yields an LP. Disjunctive cuts are generated from solutions of the LP that violate a complementarity constraint (i.e., $x_i > 0$ and $y_i > 0$) through the observation that both variables are basic and by applying standard disjunctive arguments to the corresponding tableau rows.

Disjunctive cuts have been proposed by Audet *et al.* [26] in the context of linear bilevel programming, where the optimality of a *lower level* subproblem is required for

a solution to be feasible for the *upper level* problem, and is enforced through complementarity constraints.

Quadratically Constrained Quadratic Programming (QCQP). Saxena *et al.* [27,28] proposed two classes of disjunctive cuts for quadratically constrained quadratic programming (QCQP) problems, which contain constraints of the type $x^\top Qx + b^\top x + c \leq 0$, that is, nonconvex because in general $Q \not\succeq 0$. These problems are reformulated as LPs with an extra nonconvex constraint of the form $Y = xx^\top$, where Y is an $n \times n$ matrix of auxiliary variables. Relaxing these constraints to $Y - xx^\top \succeq 0$, thereby allowing solutions such that $xx^\top - Y \succeq 0$, leads to a (convex) semidefinite program, which yields good lower bounds [29,30].

Saxena *et al.* [27,28] used the nonconvex constraint $xx^\top - Y \succeq 0$, which is relaxed in the above relaxation, to obtain disjunctive cuts. Disjunctions are derived from the nonconvex constraint $(v^\top x)^2 \geq v^\top Y v$, where vector v is obtained from the negative eigenvalues of the matrix $\bar{x}\bar{x}^\top - \bar{Y}$, and $(\bar{x}, \bar{Y})$ is a solution of the relaxation. In the second paper [27], this procedure is refined to generate cuts for the nonreformulated problem, thus avoiding the need of the auxiliary matrix variable Y .

Generalized Disjunctive Programming

Generalized disjunctive programming (GDP) is an extension of disjunctive programming [1] originally proposed in Ref. 31 as a modeling framework (with a branch-and-bound based general-purpose solution algorithm) targeting problems in chemical engineering and process synthesis. GDP explicitly formulates conditional constraints via Boolean variables and logic formulæ. This emphasizes the role that logic-based transformations (such as De Morgan’s laws or passing from conjunctive to disjunctive normal forms) have on the formulation. Furthermore, it allows the specification of different lower bounding problems.

The GDP is formulated as follows:

$$\min f(x) + \sum_{k \in K} c_k, \quad (9)$$

$$g(x) \leq 0, \quad (10)$$

$$\forall k \in K \quad \bigvee_{i \in D_k} (Y_{ik} \wedge c_k = \gamma_{ik} \wedge r_{ik}(x) \leq 0), \quad (11)$$

$$\Omega(Y) \wedge x \in X \subseteq \mathbb{R}^n \wedge c \in \mathbb{R}^{|K|}, \quad (12)$$

where K and D_k ($k \in K$) are sets of indices, γ_{ik} is a known parameter for all $k \in K, i \in D_k$, Y are Boolean and x, c are continuous decision variables, Ω is a conjunctive normal form (CNF) logic formula having free variables Y and containing the clauses $\bigvee_{i \in D_k} Y_{ik}$ for all $k \in K$, with $\bigvee$ denoting “exclusive or.” The formula $\Omega(Y)$ acts as a constraint in the sense that it should be true in order for Y to be a feasible solution of Equations (9)–(12).

It is clear that Equations (9)–(12) can be reformulated to an MINLP by replacing $c_k = \gamma_{ik}$ by $Y_{ik}(c_k - \gamma_{ik}) = 0$ and $r_{ik}(x) \leq 0$ by $Y_{ik}r_{ik}(x) \leq 0$, and writing $\Omega(Y)$ as the corresponding Boolean expression in the $\{0, 1\}$ -variables Y . When X is a vector of nonempty intervals (say $[0, U]$), the products involving the Y variables can be further reformulated to “big-M” type constraints, which are convex whenever $r_{ik}(x)$ are convex. Thus, a “big-M” convex relaxation can be easily obtained from Equations (9)–(12) using well-known techniques on the possibly nonconvex functions f and g [32]. The interest of formulations (9)–(12), however, is that it can be used to yield a different convex relaxation [33] which is in general stronger than the “big-M” one, and rests on a convex-hull type reformulation of the disjunctive constraints of Equation (11):

$$\forall k \in K \quad x = \sum_{i \in D_k} v^{ik},$$

$$\forall k \in K \quad c_k = \sum_{i \in D_k} \lambda_{ik} \gamma_{ik},$$

$$\sum_{i \in D_k} \lambda_{ik} = 1,$$

$$\begin{aligned}
\forall k \in K, i \in D_k \quad \lambda_{ik} r_{ik}(v^{ik}/\lambda_{ik}) &\leq 0; \\
\forall k \in K, i \in D_k \quad 0 \leq v^{ik} &\leq \lambda_{ik} U; \\
\forall k \in K, i \in D_k \quad \lambda_{ik} &\in [0, 1].
\end{aligned}$$

BRANCHING ON GENERAL DISJUNCTIONS

Within the context of a branch-and-bound algorithm [34], a key decision that has to be repeatedly taken is how to divide a problem into subproblems. Indeed, branch-and-bound makes an implicit use of the concept of disjunction: whenever we are not able to solve a problem $\mathcal{P}$ of the form of Equation (1), we choose a disjunction D of the feasible region of $\mathcal{P}$ (i.e., a disjunction D of the form of Equation (2) valid for S), and we divide $\mathcal{P}$ into two or more subproblems $\mathcal{P}_1, \dots, \mathcal{P}_q$ corresponding to the q terms of the disjunction; this is equivalent to solving the subproblems of Equation (3). Hence, we are guaranteed that the optimal solution of one of the q subproblems coincides with the optimum of $\mathcal{P}$. In this case, we say that we *branch on the disjunction* D . Clearly, this process can be iterated. The choice of the disjunction D at each branching step determines the effectiveness of solving Equation (1) with this approach, that is, the number of subproblems (Eq. 3) that need to be solved to find (and certify) the optimal solution of Equation (1). Of course, we are interested in finding disjunctions that generate subproblems (Eq. 3) which are as easy to solve as possible.

In MILP, branching is typically done on two-term disjunctions, and in particular, the standard method is to branch on a single variable, that is, an *elementary* disjunction. Let x^* be the solution to the LP relaxation of the current problem $\mathcal{P}$, and let $i \in N^I$ such that $x_i^* \notin \mathbb{Z}$. Then, we branch on the variable x_i by dividing $\mathcal{P}$ into $\mathcal{P}_0$ and $\mathcal{P}_1$, where $\mathcal{P}_0$ is equal to $\mathcal{P}$ with the addition of the constraint $x_i \leq \lfloor x_i^* \rfloor$, and $\mathcal{P}_1$ is equal to $\mathcal{P}$ with the addition of the constraint $x_i \geq \lceil x_i^* \rceil$. Choosing which variable should be branched on at each step is of fundamental importance for the performance of branch-and-bound. We refer to Achterberg *et al.* [35] for a recent survey on this topic.

Even though branching on single variables is the method currently implemented

by solvers for integer programs (both linear and nonlinear), it need not be so. For MILPs, branching can be done on any split disjunction of the form of Equation (6). By integrality, every feasible solution to $\mathcal{P}$ satisfies any split disjunction. In the branching literature, every disjunction which is not elementary is labeled as a *general* disjunction. Several approaches to branch on general disjunctions have been proposed in the MILP literature. These approaches can be ascribed to one of two categories. The first category contains methods that try to identify “thin” directions of the polyhedron P associated with the LP relaxation of the MILP; the second category focuses on improving as much as possible, the LP bound at the children nodes. The concept of thin direction requires the concept of *width* of a full-dimensional polyhedron P along a direction u , which is defined as $\max_{x,y \in P}(ux - uy)$. Thus, for a *pure* integer program associated with P , the *integer width* is defined as

$$\min_{\pi \in \mathbb{Z}^n \setminus \{0\}} \max_{x,y \in P}(\pi x - \pi y).$$

This definition naturally extends to the mixed integer linear case by considering integer directions $\pi \in \mathbb{Z}^n \setminus \{0\}$ with $\pi_j = 0$ for $j \notin N^I$. Mahajan and Ralphs [36] discussed the formulation of optimization models to select both thin directions and split disjunctions that yield maximum bound improvement. Note that both the problems of finding a disjunction with smallest integer width or largest bound improvement are strongly NP-hard [37].

Branching on Thin Directions

Branching on thin directions of the polyhedron P associated with the LP relaxation of the MILP is a method that derives from the work of Lenstra [38] on solving integer programs in fixed dimension in polynomial time [39,40]. The idea is as follows: First, some thin directions of P are computed, using the lattice basis reduction algorithm by Lenstra *et al.* [41]. Then, the space is transformed so that these directions correspond to unit vectors, and the problem is solved by branch-and-bound in the new space. Branching on simple disjunctions in this space translates

back to branching on general disjunctions in the original space. This method has proven successful for some particular instances where standard branch-and-bound fails because of the huge size of the enumeration tree: Aardal *et al.* [42] discussed the solution of the difficult market split instances [43], while Krishnamoorthy and Pataki studied decomposable knapsack problems [44]; see also the study by Mehrotra and Li [45].

Branching for Maximum Bound Improvement

Another line of research which has been pursued is that of selecting a good general disjunction for branching at each node of the branch-and-bound tree, in order to improve as much as possible the bound at the children nodes. Owen and Mehrotra [46] proposed branching on split disjunctions with coefficients in $\{-1, 0, 1\}$ on the integer variables with fractional values at the current node. They generate all possible such disjunctions, and evaluate them using strong branching [35], in order to select the one that gives the largest improvement of the dual bound. Karamanov and Cornuéjols [47] provided a computational study of branching on the split disjunctions that define the mixed integer gomory cuts [13] associated with the optimal simplex tableau of the current branch-and-bound node. Several such disjunctions are generated, using the quality of the underlying cut as a proxy for the strength of the disjunction, and strong branching is used to select one. A similar approach was proposed by Cornuéjols *et al.* [48], but instead of considering the split disjunctions associated with MIG cuts that can be read directly from the optimal simplex table, an improvement step is applied first: the rows of the simplex table are linearly combined with integer coefficients in order to reduce the coefficients of the resulting combination. This step corresponds to tilting the underlying disjunctions so as to produce stronger MIG cuts (see also the reduce-and-split algorithm by Andersen *et al.* [49]).

DISJUNCTIVE PROGRAMMING

EGON BALAS

Tepper School of Business,
Carnegie Mellon University,
Pittsburgh, Pennsylvania

Disjunctive programming is optimization over unions of polyhedra [1–3]. While polyhedra are convex, their unions are obviously not. To put it differently, disjunctive programming is optimization over disjunctive sets. A disjunctive set is a set defined by linear inequalities connected by conjunction ($\wedge$, “and,” juxtaposition), disjunction ($\vee$, “or”), or negation ($\neg$, “complement of”). The name reflects the fact that of the above three operations, it is the disjunction that makes the sets defined in this way nonconvex. Pure and mixed integer programs, in particular pure and mixed 0–1 programs, can be viewed as disjunctive programs but the same is true of a host of other problems; for instance, the linear complementarity problem. The main application of disjunctive programming has, so far, been in 0–1 programming, where it has served as the source of a rich family of cutting planes and in the early 1990s has produced a computationally successful variant known as lift-and-project cuts.

The basic concepts of disjunctive programming can be expressed using linear inequalities $a^i x \geq b_i$ and the halfspaces H_i^+ defined by them as building blocks. Thus, the intersection of a finite number of halfspaces, $P = \cap_{i \in M} H_i^+$, is a polyhedron; while the union of a finite number of halfspaces, $D = \cup_{i \in M} H_i^+$, is an *elementary* disjunctive set. A disjunctive set can be stated in many equivalent forms, of which the two extremes are the *conjunctive* normal form and the *disjunctive* normal form. The first one is a conjunction, or intersection, of elementary disjunctive sets $\cap_{i \in T} D_i$, while the second one is a disjunction, or union, of polyhedra $\cup_{i \in Q} P_i$. Since any disjunctive set can be brought to any of these extreme forms by a finite number of simple operations [4],

disjunctive programming can be defined as optimization over unions of polyhedra.

The two central results of disjunctive programming can be stated succinctly as follows:

1. There is a compact representation of the convex hull of a union of polyhedra in a higher-dimensional space, which in turn can be projected back into the original space. The first step of this operation, that is the higher-dimensional representation, may be viewed as lifting (or extended formulation), while the second step is projection. As a result, one obtains the convex hull in the original space.
2. A large class of disjunctive sets, called *facial*, among them mixed 0–1 programs, can be convexified sequentially; that is, their convex hull can be derived by imposing the elementary disjunctions of their conjunctive normal form one at a time, generating the convex hull of the current set each time.

Beyond these specific results, the basic idea of disjunctive programming that the reformulation of a given problem in a higher dimensional space can often lead to a more advantageous problem structure, has turned out to be a very fruitful one with countless applications in combinatorial optimization [5–7].

ORIGINS

Historically and conceptually, disjunctive programming originates in the work around 1970 on intersection cuts for mixed integer programs [8–10]. Suppose the linear programming relaxation of a mixed integer program has an optimal basic solution expressed in the form

$$x = \bar{x} - \sum_{j \in J} \bar{a}_j s_j, \quad (1)$$

Figure 1. Intersection cut from (a) cone C , (b) strip C .

where $\bar{x}$ is the (fractional) solution in question; $s_j \geq 0, j \in J$, are the nonbasic variables; and we are interested in generating a valid cutting plane (i.e., an inequality violated by $\bar{x}$, but satisfied by all feasible integer points). One way of doing this is by choosing a suitable closed convex set C , namely one whose interior contains $\bar{x}$ but no feasible integer point and intersecting the boundary of C with the n halfplanes $\bar{x} - \bar{a}_j s_j, s_j \geq 0, j \in J$. The hyperplane through the n intersection points $s_j^*, j \in J$, then defines a valid cutting plane, the *intersection cut*. In the space of the s -variables, it has the form $\alpha s \geq 1$, with $\alpha_j = \frac{1}{s_j^*}$, where $s_j^* = \max\{s_j : \bar{x} - \bar{a}_j s_j \in C\}$. Figure 1 (a) and (b) illustrate intersection cuts. In both cases, the convex set C consists of the intersection of two halfspaces, but in (a) the intersection of the halfspaces is a cone, whereas in (b) the halfspaces are defined by hyperplanes parallel to each other and so their intersection is an infinite strip. The intersection cut from this latter set C is the mixed integer Gomory (MIG) cut.

The connection with disjunctive programming becomes clear if we consider an intersection cut from a polyhedral set $C := \{x : d^i x \leq d_0^i, i = 1, \dots, q\}$. Then the condition that the interior of C contain no feasible integer point, is equivalent to the condition that every feasible integer point should satisfy at least one of the weak complements of the inequalities defining C , that is should satisfy the disjunction

$$\bigvee_{i=1}^q (d^i x \geq d_0^i). \quad (2)$$

So an intersection cut from C can be viewed as a disjunctive cut from (2). While these two cuts are the same, the disjunctive point of view opens up new perspectives. Thus, suppose in addition to (2), all feasible solutions have to satisfy $Ax \geq b$. Then one way to proceed would be to generate all valid cutting planes from (2) and append them to $Ax \geq b$, resulting in the constraint set

$$P := \left\{ x \in \mathbb{R}^n : (Ax \geq b) \cap \text{conv} \left(\bigvee_{i=1}^q (d^i x \geq d_0^i) \right) \right\}.$$

But another way to proceed is to introduce $Ax \geq b$ into every term of the disjunction 2, that is replace (2) by

$$\bigvee_{i=1}^q \left(Ax \geq b \right) \quad (3)$$

and take the convex hull of this union of polyhedra

$$\bar{P} := \text{conv} \left(\bigvee_{i=1}^q \left(Ax \geq b \right) \right).$$

Now it is easy to see that $\bar{P} \subseteq P$, but the fact is that except for some special cases [4], $\bar{P} \neq P$, that is $\bar{P}$ is tighter than P .

THE CONVEX HULL OF A UNION OF POLYHEDRA

Disjunctive programming has two characterizations of the (closed) convex hull of a union of polyhedra.

Let

$$F := \bigcup_{i \in Q} P_i, P_i := \{x \in \mathbb{R}^n : A^i x \geq b^i\} \neq \emptyset, \\ \text{with } A_{m_i \times n}^i, i \in Q. \quad (4)$$

Theorem 1 [1,4].

$$\text{cl conv } F \\ = \{x \in \mathbb{R}^n : x - \sum_{i \in Q} y^i = 0, \\ A^i y^i - b^i y_0^i \geq 0, \\ y_0^i \geq 0 \quad i \in Q, \quad (5) \\ \sum_{i \in Q} y_0^i = 1, \\ \text{for some } (y^i, y_0^i) \in \mathbb{R}^{n+1}, i \in Q\}.$$

This theorem gives a polyhedral representation of the convex hull of a union of $q = |Q|$ polyhedra in a higher-dimensional space, one whose dimension is linear in q , the number of polyhedra in the union: it is thus a compact representation. In the form stated above, it assumes that the polyhedra are nonempty. However, the theorem remains valid without this assumption, provided that the following condition is satisfied: if any of the empty polyhedra has directions of infinity (i.e., solutions to the homogeneous system $A^i x \geq 0$), such directions must belong to the sum of the recession cones of the nonempty polyhedra.

In the special case of a disjunction of the form $x_j \in \{0, 1\}$, when $|Q| = 2$ and

$$P_{j0} := \{x \in \mathbb{R}_+^n : Ax \geq b, x_j = 0\}, \\ P_{j1} := \{x \in \mathbb{R}_+^n : Ax \geq b, x_j = 1\},$$

$\text{cl conv}(P_{j0} \cup P_{j1})$ is the set of those $x \in \mathbb{R}^n$ for which there exist vectors $(y, y_0), (z, z_0) \in \mathbb{R}_+^{n+1}$ such that

$$\begin{array}{rcl} x - y & - z & = 0, \\ Ay - by_0 & & \geq 0, \\ -y_j & & = 0, \\ & Az - bz_0 & \geq 0, \\ & z_j - z_0 & = 0, \\ y_0 + z_0 & & = 1, \end{array} \quad (6)$$

a system of quite manageable size.

The second description of the convex hull of a union of polyhedra is obtained by projecting the system (5) onto the subspace of the x -variables.

Theorem 2 [1,2].

$$\text{cl conv } F \\ = \{x \in \mathbb{R}^n : \alpha x \geq \beta \text{ for all } (\alpha, \beta) \in \mathbb{R}^{n+1} \\ \text{such that} \\ \alpha = u^i A^i, \beta \leq u^i b^i, i \in Q, \\ \text{for some } u^i \in \mathbb{R}^{m_i}, u^i \geq 0, i \in Q\}. \quad (7)$$

This theorem can be viewed as a Farkas lemma for disjunctive systems, or unions of polyhedra. For a single polyhedron or system of inequalities $Ax \geq b$, one version of the Farkas lemma asserts that an inequality $\alpha x \geq \beta$ is a consequence of $Ax \geq b$ if and only if there exists a vector $u \geq 0$ such that $\alpha = uA, \beta \leq ub$. Viewed in this light, Theorem 2 asserts that given a disjunctive set or union of polyhedra of the form of (4), an inequality $\alpha x \geq \beta$ is a consequence of (is implied by, is valid for) the disjunctive set (the union of polyhedra) if and only if it is a consequence of (is implied by, is valid for) each consistent member $A^i x \geq b^i$ of the union (here consistent means $P_i \neq \emptyset$).

This second characterization is directly relevant to the task of generating valid cuts for $\text{cl conv } F$, since stating it in a slightly different form, it asserts that $\alpha x \geq \beta$ is valid for F if and only if there exist vectors $u^i \in \mathbb{R}_+^{m_i}, i \in Q$, such that

$$\begin{aligned} \alpha &\geq \sup_{i \in Q} u^i A^i, \\ \beta &\leq \inf_{i \in Q} u^i b^i. \end{aligned} \quad (8)$$

In other words, all valid cuts for F are of the form of (8).

The family of all valid inequalities for F is the reverse polar cone of F , defined as $F^\# := \{(\alpha, \beta) \in \mathbb{R}^{n+1} : \alpha x \geq \beta \text{ for all } x \in F\}$. In particular, from Theorem 2 it follows that

$$F^\# = \{(\alpha, \beta) \in \mathbb{R}^{n+1} : \alpha = u^i A^i, \beta \leq u^i b^i \\ \text{for some } u^i \geq 0, i \in Q\}$$

and we have the following characterization of the facets of $\text{cl conv } F$. Let β be fixed, $\beta \neq 0$, and $F_\beta^\# = \{\alpha \in \mathbb{R}^n : (\alpha, \beta) \in F^\#\}$.

Theorem 3 [1,2]. *Let F be full-dimensional. Then the inequality $\alpha x \geq \beta$ defines a facet of $\text{cl conv } F$ if and only if α is a vertex of $F_\beta^\#$.*

Analogous results are known for the cases when F is less than full dimensional and/or $\beta = 0$.

From these results, it follows that the facets of the convex hull of F , and more generally, all valid inequalities $\alpha x \geq \beta$ for F , can be found by minimizing some properly chosen objective function over the constraint set of $F_\beta^\#$; that is, by solving a linear program of the form

$$\begin{aligned} \min \{g\alpha : \alpha & - u^i A^i = 0 \\ & u^i b^i \geq \beta \\ & u^i \geq 0, \quad i \in Q\}, \end{aligned} \quad (9)$$

for some appropriate vector $g \in \mathbb{R}^n$. It can be shown [1] that the linear program of (9) has a finite minimum if and only if $\lambda g \in \text{cl conv } F$ for some $\lambda > 0$; that is, if and only if g belongs to the cone generated by F ; and should g satisfy this condition, $\bar{\alpha}x \geq \beta$ defines a facet of $\text{cl conv } F$ (where F is assumed to be full dimensional), if and only if $\alpha = \bar{\alpha}$ for every optimal solution (α, u) of (9). This last condition is needed to guarantee that α is a vertex of $F_\beta^\#$.

FACIAL DISJUNCTIVE PROGRAMS

Given a disjunctive program in conjunctive normal form, that is as a conjunction of elementary disjunctive sets, the question arises whether it is possible to generate the convex hull of feasible points by imposing the elementary disjunctions one by one, at each step computing the convex hull of the set defined by the disjunctions imposed in the earlier steps, plus the new one. The answer is negative in general, but positive for an important class of disjunctive programs called *facial*. This class includes (pure or

mixed) 0–1 programs, but not general (pure or mixed) integer programs.

Consider a disjunctive program with constraint set

$$F := \{x \in F_0 : \bigvee_{i \in Q_j} (d^i x \geq d_0^i), j \in S\}, \quad (10)$$

where $F_0 := \{x \in \mathbb{R}^n : Ax \geq b\}$.

Then F is called *facial* if every term $d^i x \geq d_0^i$ of every elementary disjunction indexed by S defines a face of F_0 (in other words, if $F_0 \cap \{x : d^i x > d_0^i\} = \emptyset, i \in Q_j, j \in S$).

Theorem 4 [1,2]. *Let F be as in (10). For an arbitrary ordering of $S := \{1, \dots, t\}$, define recursively*

$$F_j := \text{conv} \left(F_{j-1} \cap \left\{ x : \bigvee_{i \in Q_j} (d^i x \geq d_0^i) \right\} \right), \quad j = 1, \dots, t.$$

Then $F_t = \text{conv } F$.

The most important class of facial disjunctive programs are mixed 0–1 programs and for this case, the above theorem asserts that the convex hull of

$$F := \{x \in \mathbb{R}^n : Ax \geq b, x_j \in \{0, 1\}, j = 1, \dots, p \leq n\}$$

can be obtained in p steps, through a procedure that at each step imposes one new disjunction, $x_j \leq 0 \vee x_j \geq 1$, and generates the convex hull of the resulting two-term disjunctive set

$$\{x \in F_{j-1} : x_j \leq 0\} \cup \{x \in F_{j-1} : x_j \geq 1\}.$$

With this result, disjunctive programming theory has established the most important distinguishing feature of 0–1 programs among integer programs, namely sequential convexifiability. Figure 2 illustrates the fact that general integer programs, even when the integers are bounded between 0 and 2, are not sequentially convexifiable: the convex hull of the integer points in the shaded area of Fig. 2(a) is the line joining them in Fig. 2(d), but sequential convexification ends with the set in Fig. 2(c).

Figure 2. General integer programs are not sequentially convexifiable.

The significance of this property becomes obvious when it comes to classifying valid inequalities. A mixed integer Gomory (MIG) cut is said to be of *Chvátal rank* k if its derivation requires at least k recursive applications of integer rounding. In the same spirit, the *disjunctive rank* of a valid inequality for a disjunctive set is defined as the minimum number of recursive iterations of the abovementioned sequential convexification procedure needed to derive it. It then follows that the disjunctive rank of any valid inequality for a mixed 0–1 program can never exceed the number of 0–1 variables. This is in sharp contrast with the disjunctive rank—or for that matter, with the Chvátal rank—of a valid inequality for a general mixed integer program, for which no such bound exists.

LIFTING AND PROJECTION

A key idea of disjunctive programming is that a disjunctive program is equivalent to

a linear program in a higher-dimensional space (Theorem 1). This makes it possible to generate strong cuts for the original problem by solving a higher-dimensional linear program. Historically, the implementation of the disjunctive programming approach into a practical 0–1 programming algorithm required not only the choice of a specific version of disjunctive cuts, but also a judicious combination of cutting with branching, made possible in turn by the discovery of an efficient procedure for lifting cuts generated in a subspace (for instance, at a node of the search tree) to be valid in the full space (i.e., throughout the search tree). The particular version that turned out to be computationally successful is known as lift-and-project [11].

Suppose we wish to generate strong cuts for a mixed integer 0–1 program, whose linear programming relaxation has the constraint set $Ax \geq b$ (notice that this subsumes $x \geq 0$ and the inequalities $x_j \leq 1$ for the integer-constrained variables) and

the optimal solution $\bar{x}$. Then the linear program (9), restated for the disjunction $x_j = 0 \vee x_j = 1$, with the objective of cutting off $\bar{x}$ by a maximum amount (i.e., generating a “deepest cut”) and with its constraint set normalized, becomes the “cut generating linear program” for x_j :

$$\begin{aligned}
\min \quad & \alpha \bar{x} - \beta \\
\text{s.t.} \quad & \alpha - uA + u_0 e_j \geq 0, \\
& \alpha - vA - v_0 e_j \geq 0, \\
& -\beta + ub = 0, \\
& -\beta + vb + v_0 = 0, \\
& ue + ve + u_0 + v_0 = 1, \\
& u, v \geq 0.
\end{aligned} \tag{CGLP}_j$$

Here, $e = (1, \dots, 1)$ and e_j is the j -th unit vector.

The last equation has the purpose of truncating the cone defined by the rest of the constraint set. Several other normalizations are possible, such as $\beta \in \{1, -1\}$ or $\|\alpha\|_1 \leq 1$, with pros and cons for each one and their choice plays an important role in determining the optimum; different normalizations can yield different optimal solutions, that is different “deepest” cuts, for the same objective function.

Solving $(\text{CGLP})_j$ yields a cut $\alpha x \geq \beta$, where $\beta = ub = vb + v_0$, and

$$\alpha_k = \begin{cases} \max\{ua_k, va_k\} & k \in N \setminus \{j\}, \\ \max\{ua_j - u_0, va_j + v_0\} & k = j, \end{cases} \tag{11}$$

with N the column index set and a_k the k -th column of A .

From Theorem 2, the solution set of $(\text{CGLP})_j$ gives the coefficient vectors (α, β) of all the valid inequalities for the set $\{x \in \mathbb{R}^n : Ax \geq b, x_j \in \{0, 1\}\}$; and from Theorem 3, if we generate all the cuts corresponding to basic solutions of $(\text{CGLP})_j$, we obtain the convex hull of this set.

If we then iterate this procedure for all x_h , $h \neq j$, from Theorem 4 (on sequential convexification) we obtain the convex hull

of $\{x \in \mathbb{R}^n : Ax \geq b, x_h \in \{0, 1\}, h \in N_1\}$, where N_1 is the set of integer-constrained variables.

In a practical algorithm of course one cannot generate all the cuts and the objective is to generate a collection of “strong” cuts and make the best use of them, possibly in combination with a branch and bound procedure. The particular structure of disjunctive cuts of the type (11) has made it possible to avoid a major stumbling block on the way to combine cutting planes with branch-and-bound. A cutting plane derived at a node of the search tree defined by a subset $B_0 \cup B_1$ of the 0–1 variables, where B_0 and B_1 index those variables fixed at 0 and 1, respectively, is valid at that node and its descendants in the tree (where the variables in $B_0 \cup B_1$ remain fixed at their values). Such a cut can, in principle, be made valid at other nodes of the search tree, where the variables in $B_0 \cup B_1$ are no longer fixed, by calculating appropriate values for the coefficients of these variables—a procedure called *lifting*. However, calculating such coefficients is in general a daunting task, which may require the solution of an integer program for every coefficient. One important advantage of the cuts discussed here is that the multipliers u, u_0, v, v_0 obtained along with the cut vector (α, β) by solving $(\text{CGLP})_j$ can be used to calculate by closed form expressions the coefficients α_h of the variables $h \in B_0 \cup B_1$.

While this possibility of calculating efficiently the coefficients of variables absent from a given subproblem (i.e., fixed at certain values) is crucial for making it possible to generate cuts during a branch-and-bound process that are valid throughout the search tree, its significance goes well beyond this aspect. Indeed, most columns of A corresponding to nonbasic components of $\bar{x}$ typically play no role in determining the optimal solution of $(\text{CGLP})_j$ and can therefore be ignored. In other words, the cuts can be generated in a subspace involving only a subset of the variables, and then lifted to the full space. This is the procedure followed in Ref. 12, where the subspace used is that of the variables indexed by some $R \subset N$, such that R includes all the 0–1 variables that are fractional and all the continuous variables

that are positive at the LP optimum. The lifting coefficients for the variables not in the subspace, which are all assumed w.l.o.g. to be at their lower bound, are then given by $\alpha_\ell := \max\{ua_\ell, va_\ell\}$, $h \in N \setminus R$, where u and v are the optimal vectors obtained by solving (CGLP)_j.

The cut $\alpha x \geq \beta$ derived from a disjunction of the form $x_j \in \{0, 1\}$ can be strengthened by using the integrality conditions on variables other than x_j [2,13]. Indeed, if x_k is such a variable, the coefficient $\alpha_k = \max\{ua_k, va_k\}$ can be replaced by

$$\bar{\alpha}_k := \min\{ua_k + u_0 \lceil m_k \rceil, va_k - v_0 \lfloor m_k \rfloor\}, \quad (12)$$

where

$$m_k := \frac{va_k - ua_k}{u_0 + v_0}.$$

This strengthening procedure can also be applied to cuts derived from disjunctions other than $x_j \in \{0, 1\}$, including disjunctions with more than two terms. In the latter case, however, the closed form expression for the values m_k used above has to be replaced by a procedure for calculating those values, whose complexity is linear in the number of terms in the disjunction (see Refs 2 and 13 for details).

The strengthened lift-and-project cuts (12) have been shown to be in 1–1 correspondence with MIG cuts [14]. To be more precise, an MIG cut from the x_k row of the optimal simplex tableau is equivalent to the lift-and-project cut $\alpha x \geq \beta$ corresponding to the basic solution (α, u, v, u_0, v_0) of (CGLP)_k in which $u = v = 0$ and $u_0 = 1/a_{k0}$, $v_0 = 1/(1 - a_{k0})$. The lift-and-project cuts corresponding to other basic solutions of (CGLP)_k are equivalent to MIG cuts from the x_k row of other (possibly infeasible) simplex tableaus. The precise correspondence established in Ref. 14 between bases of the LP and those of the CGLP make it possible to mimic on the LP tableau the solution procedure of the CGLP, without explicitly formulating the latter. From this perspective, finding the “deepest” lift-and-project cut amounts to pivoting in the LP tableau in order to find a tableau (whether feasible or not) whose x_k row yields the “deepest” MIG cut [14,15].

The lift-and-project procedure with its cut-generating linear program can also be derived in an alternative way, by the following procedure:

1. Choose $x_j \in \{0, 1\}$. Multiply $Ax \geq b$ with x_j and $1 - x_j$ to obtain the system $x_j(Ax - b) \geq 0$, $(1 - x_j)(Ax - b) \geq 0$.
2. Linearize the resulting system by substituting y_i for $x_i x_j$, $i = 1, \dots, n$, and x_j for x_j^2 .
3. Project the resulting polyhedron onto the x -space.

It is not hard to see that the outcome of steps 1 and 2 is precisely the system 6; that is, the higher-dimensional representation of $\text{conv}(P_{j0} \cup P_{j1})$ known from disjunctive programming [1]. Furthermore, step 3 results in the projection of (6) onto the x -space, which is precisely the constraint set of CGLP_j; that is, the system whose solutions are the coefficient vectors of all the valid inequalities for $\{x \in \mathbb{R}^n : Ax \geq b, x_j \in \{0, 1\}\}$. It is also clear from the sequential convexification Theorem 3 that iterating this procedure for all $j \in N_1$ yields the coefficient vectors of all the inequalities describing the convex hull of $\{x \in \mathbb{R}^n : Ax \geq b, x_j \in \{0, 1\}, j \in N_1\}$.

The above three-step procedure is a streamlined version of the matrix-cone procedure of Lovász and Schrijver [16]. The latter involves in step 1 multiplication with x_j and $1 - x_j$ for every $j \in N_1$ rather than just one. While obtaining the convex hull of $\{x \in \mathbb{R}^n : Ax \geq b, x_j \in \{0, 1\}, j \in N_1\}$ still involves $|N_1|$ iterations of steps 1, 2, 3, the added computational cost brings a reward: after each iteration, the coefficient matrix of the linearized system must be positive-semidefinite, a condition that tightens the constraint set. A procedure similar to this one (without the semidefiniteness implication) was proposed by Sherali and Adams [17].

SPLIT CUTS AND OTHER DISJUNCTIVE CUTS

A two-term disjunction of the form $x_k \leq 0 \vee x_k \geq 1$ is a special case of a class called *split disjunction*:

$$\pi x \leq \pi_0 \vee \pi x \geq \pi_0 + 1, \quad (13)$$

where (π, π_0) is an arbitrary vector in $\mathbb{Z}^{n+1}$. Clearly, any $x \in \mathbb{Z}^n$ satisfies 13. Cuts derived from split disjunctions are called *split cuts*. The collection of all valid split cuts added to the linear constraint set $F_0 := \{x \in \mathbb{R}^n : Ax \geq b\}$ forms the (elementary, or rank 1) split closure of F_0 , known to be a polyhedron [18]. Iterating this procedure k times gives the rank k split closure. A given cut valid for F_0 has split rank k if it can be derived from F_0 in k , but not fewer than k , iterations. It is known [18] that there is no upper bound on the split rank of inequalities needed to define the convex hull of a mixed integer set. This finding is in sharp contrast to the fact that the split rank of any inequality defining the convex hull of a mixed 0–1 set is at most equal to the number of 0–1 variables (due to the sequential convexifiability of such sets).

A number of interesting connections between intersection cuts, split cuts, lift-and-project cuts, MIG cuts, and other mixed integer programming cuts that can be derived from two-term disjunctions, are discussed in Ref. 19. The disjunctive programming characterization of the convex hull of a union of polyhedra (Theorem 1) has been extended in Ref. 20 to unions of convex sets, and used to generate cuts for mixed integer convex programs. Disjunctive cuts for mixed integer programs with non-convex constraint sets have been derived in Ref. 21.

INTRODUCTION

In Operational Research and Management Science (ORMS), discrete-event simulation has been used to analyze production and logistics problems in many areas such as commerce, defense, health, manufacturing, and logistics for many years [1]. The first discrete-event simulation languages appeared in the late 1950s. These evolved during the 1960s and 1970s. With the arrival of the IBM PC, the 1980s saw the rise of visual interactive modeling environments that allowed simulation modelers to visually create and simulate discrete-event models. These have matured into the commercial off-the-shelf simulation packages (CSPs) that are very familiar to ORMS practitioners today. They include ArenaTM (www.arenasimulation.com), AnylogicTM (www.xjtek.com), FlexsimTM (www.flexsim.com), Simul8TM (www.simul8.com), WitnessTM (www.lanner.com), etc. and simulation languages such as SLXTM and GPSS/HTM (www.wolverinesoftware.com) [2]. Each has a wide range of functionality including visual model building, simulation run support, animation, optimization, and virtual reality. Some have their own dedicated programming language and all are able to be linked to other COTS (commercial off-the-shelf) software (such as Microsoft Excel). Nearly all CSPs only run under Microsoft WindowsTM. CSPs are typically used by modelers skilled in ORMS.

What is a distributed simulation? Essentially, a distributed simulation is a set of simulations, each running on a separate computer, that interact or *interoperate* with each other to accomplish the goals of the simulation. The typical reasons for using distributed simulation are that a simulation takes a long time to run or that models need to be merged to form a larger simulation (e.g., a manufacturing model and a warehouse model merging to expand the scope of both models in a supply chain) [3–7]. Further, if one wishes to combine one or more models developed in different CSPs, as these tools do not have the ability to save models as in a format compatible with different packages (as one might when saving a Microsoft Word document as text) or to import models from different packages, interoperability is really the only alternative (other than manual conversion!) Here are some ORMS examples of where distributed simulation can be used:

- A supply chain distributes equipment to front line troops. A model is built to represent the different supply centers and transportation links to various battlefronts. Experimentation investigates the reliability of the supply chain under different threat conditions.
- An automotive company is planning to build a new factory. The manufacturing line is modeled and simulated using a CSP. Experimentation investigates how many engines can be produced in one year against different levels of resources (machines, buffers, workers, etc.).
- A regional health authority needs to plan the best way of distributing blood to different hospitals. A model is built using a CSP. Experimentation is carried out to investigate different supply policies against “normal” and emergency supply situations.
- A police authority needs to determine how many officers need to be on patrol and how many need to be in the different

police stations that it manages. A model is built and experiments are carried out to investigate staffing against different scenarios (football matches, terrorist attacks, etc.).

- A bank sells different financial products. When a new product is planned, managers need to determine the resource impact against current financial services. Using existing business process models (in Business Process Modeling Notation or BPMN for example), a new model is built and simulated. Experiments investigate different resource levels in different departments.

To reinforce why distributed simulation may be needed, consider each of the above examples. If models are geographically remote (i.e., in separate places) then distributed simulation is needed to link the models together. If models are large, then distributed simulation is needed to share the processing load over different computers. If the models are written in different packages, then distributed simulation is again needed to link the models together. For example, in the case of the regional health authority, models in different CSPs may exist in different hospitals with different data sources that are confidential and cannot be easily moved. The combined model may also be large. Distributed simulation is therefore needed in this case to *both* link the models and their different CSPs together *and* to share the processing load. Not all of the above examples may need to share the processing. However, all may need distributed simulation as a result of being in separate places and using different packages.

To investigate this topic, we now discuss distributed simulation in ORMS and its technological difficulties. We then present an approach used to simplify the realization of distributed simulations and a case study illustrating its use.

DISTRIBUTED SIMULATION IN ORMS

As outlined above, distributed simulation in ORMS will typically involve the interaction,

or interoperability, of CSP. The set of techniques used to achieve this is called *commercial off-the-shelf simulation package interoperability* (CSPI). The simple act of linking together, or interoperating, two or more CSPs and their models, can be extremely difficult. This is due to time synchronization requirements and the complexity of distributed simulation algorithms and/or software used to create the link. Let us consider briefly both these issues.

The Time Synchronization Problem

Consider two models, a manufacturing system and a warehouse. The manufacturing system passes jobs to the warehouse for storage and the warehouse passes material to the manufacturing system for processing. Each model runs in its “own” CSP running on a separate computer. Let us assume that both simulations begin at 9 a.m. Monday. Both continue to simulate their systems. However, the manufacturing system model is more complex than the warehouse model and takes longer to simulate. After half an hour in real time, the manufacturing simulation is at 3 p.m. Tuesday and the warehouse simulation is at 11 a.m. Thursday. During this time both models have been interacting. As shown in Fig. 1, the effect of this is that if the manufacturing system sends a job to the warehouse, the job arrives in the past for the warehouse model! Figure 2 shows what should occur, that is, the two models are synchronized to ensure that the event is scheduled at the correct simulation time. To prevent this when simulations interact or *interoperate*, a *time synchronization method* is needed.

Time Synchronization Methods

How can we synchronize time? Essentially, each model becomes a *logical process* (LP) or *federate* that interacts with other models by time-stamped messages that represent the interaction of one model with another (say, when an entity leaves one part of a model and arrives at another) [8]. In other words, these time-stamped messages represent events that one model “schedules” for another, that is, a job leaving our manufacturing system is scheduled to arrive at the warehouse

Figure 1. Distributed simulation without synchronization.

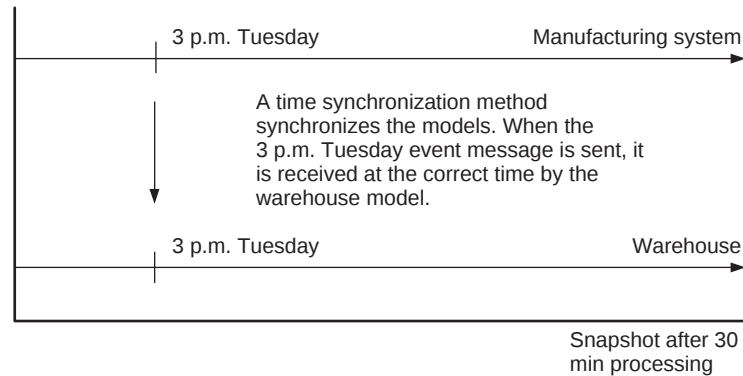

Figure 2. Distributed simulation with synchronization.

at 3 p.m. Tuesday. Time synchronization therefore involves techniques to correctly schedule that event in the destination model's event list. There are two major approaches to achieving this. *Conservative* approaches [9] do not allow any simulation to process an event until it is "safe" to do so; that is, when a simulation wishes to advance to the next event, the time synchronization approach determines if there is an event message that schedules an event before the simulation's next event time. If there is, the simulation executes that new event and repeats the process. *Optimistic* approaches in general are based on *Time Warp* [10], which instead allows simulations to process their events and to periodically check for these time-stamped event messages. If the time-stamp of an event message is in the past of the simulation, the simulation is "rolled back" to the last event before the time of the

new event message. The event message is then processed and the simulation continues. Reviews the many variants of these two approaches can be found in Ref. 11.

More recently, the "practice" of distributed simulation has been effected on a wide scale by attempts to standardize approaches. These standardization efforts took place in the mid to late 1990s and resulted in the IEEE 1516 standard *The High Level Architecture* (HLA), which supports the general needs of distributed simulation [12–15]. This is rooted in the early work by Chandy and Misra and Jefferson but considerably updates it with advances in distributed computing. The HLA defines the overall "rules," the runtime infrastructure (RTI) functions, and the format of the data that are used by a collection of models (federates) running on different computers to interact (such a collection of models is termed a *federation*) [16].

Examples of HLA RTIs include commercial RTIs from MAK (www.mak.com) and PITCH (www.pitch.se), and the service-oriented high-level architecture runtime infrastructure (SOHR) [17]. In HLA terms, a simulated model is a *federate*, and a collection of such models is termed a *federation*. The HLA specification supports different time synchronization approaches and has to some extent simplified the creation of a distributed simulation. However, the full specification runs to several hundred pages and the creation of a distributed simulation is a considerable task. In reality, distributed simulation is a very complex field that utilizes quite complex technologies. It is the purpose of this article to present distributed simulation from an ORMS viewpoint, that is, one that hides much of the complexities of distributed simulation and “exposes” those issues that should only concern ORMS end users.

Figure 3 shows the problem outlined above. A distributed simulation or federation is composed of a set of CSPs and

their models. Each model/CSP represents a federate normally running on its own computer. In a distributed simulation, each model/CSP federate therefore exchanges data directly or via an RTI implemented over a network in a time-synchronized manner (as denoted by the thick double-headed arrow). Federate F1 consists of the model M1 and the CSP1 and federate F2 consists of the model M2 and the simulation package CSP2. Note that A, Q, and R are generic symbols that represent activities, queues, and resources, respectively, and can be mapped onto any corresponding CSP objects (such as workstations, storage bins, etc.) In this case, federate F1 publishes and sends information to the RTI in an agreed format and time-synchronized manner, and federate F2 must subscribe to and receive that information in the same agreed format and time-synchronized manner; that is, both federates must agree on a common representation of data and both must use the RTI in a similar way. To further complicate matters,

Figure 3. The COTS simulation package interoperability problem.

the “passing” of entities and the sharing of resources require different distributed simulation protocols. In entity passing, the departure of an entity from one model and the arrival of an entity at another can be the same scheduled event in the two models: most distributed simulations represent this as a time-stamped event message sent from one federate to another. The sharing of resources cannot be handled in the same way. For example, when a resource is released or an entity arrives in a queue, a CSP executing the simulation will determine if a workstation can start processing an entity. If resources are shared, each time an appropriate resource changes state, a time-stamped communication protocol is required to inform and update the changes of the shared resource state. Further problems arise when we begin to “dig” further into the subtleties of interoperability. In the next section we consider what has been done to simplify the implementation of ORMS distributed simulations and CSP interoperability.

COTS SIMULATION PACKAGE INTEROPERABILITY

There are several published examples of how distributed simulations have been created with CSPs. The first major work in the area was done by Straßburger [18]. Various strategies, implementations, and applications have been investigated since then. Illustrations of different approaches that have been used to create ORMS distributed simulations with CSPs can be found in Refs 19–37. This work, while contributing to the development of a distributed simulation, presents a problem. There is a variety of different approaches to distributed simulation with CSPs. As argued in Ref. 38, a common approach is needed. To standardize this approach, an international standardization group—Simulation Interoperability Standards Organization’s Commercial Off-The-Shelf Simulation Package Interoperability Product Development Group (CSPI PDG)—has produced a set of draft standards in this area, which is described initially in Ref. 36. The distributed approach used in this article is based on the

standards being developed by the CSPI PDG and can be found in full in Refs 39 and 40.

To simplify the process of generating a distributed simulation, the CSPI PDG has created a standardized set of interoperability reference models (IRMs) or “interoperability design patterns,” which attempt to capture these subtleties. These are effectively a set of simulation patterns or templates that enable modelers, vendors, and solution developers to specify the interoperability problems that must be solved. The IRMs are intended to be used as follows:

- To clearly *identify* the model/CSP interoperability *capabilities* of an *existing* distributed simulation; for example, the distributed supply chain simulation is compliant with IRMs Type A.1, A.2 and B.1;
- To clearly *specify* the model/CSP interoperability *requirements* of a *proposed* distributed simulation; for example, the distributed hospital simulation must be compliant with IRMs Type A.1 and C.1.

An IRM is defined as the simplest representation of a problem within an identified interoperability problem type. Each IRM can be subdivided into different subcategories of problem. As IRMs are usually relevant to the boundary between two or more inter-operating models, models specified in IRMs are as simple as possible to “capture” the interoperability problem and to avoid possible confusion. These simulation models are intended to be representative of real model/CSPs but use a set of “common” model elements that can be mapped onto specific (generalized) CSP elements. Where appropriate, IRMs specify time synchronization requirements and present alternatives. IRMs are intended to be cumulative (i.e., some problems may well consist of several IRMs). Most importantly, IRMs are intended to be understandable by simulation developers, CSP vendors, and technology solution providers.

Interoperability Reference Model Types

There are currently four different types of IRM. These are

Type A: entity transfer
 Type B: shared resource
 Type C: shared event
 Type D: shared data structure.

Briefly, IRM Type A, entity transfer, deals with the requirement of transferring entities between simulation models, such as an entity *Part* leaving one model and arriving at the next. IRM Type B, shared resource, refers to sharing of resources across simulation models. For example, a resource *R* might be common between two models and represents a pool of workers. In this scenario, when a machine in a model attempts to process an entity waiting in its queue it must also have a worker. If a worker is available in *R*, then processing can take place. If not, the work must be suspended until one is available. IRM Type C, shared event, deals with the sharing of events across simulation models. For example, when a variable within a model reaches a given threshold value (a quantity of production, an average machine utilization, etc.), it should be able to signal this fact to all models that have an interest in this fact (to throttle down throughput, route materials via a different path, etc.). IRM Type D, shared data structure, deals with the sharing of variables and data structures across simulation models. Such data structures are semantically different from resources, for example, a bill of materials or a common inventory. We now introduce the most commonly used IRM.

IRM TYPE A: ENTITY TRANSFER

Overview

IRM Type A, entity transfer, represents interoperability problems that can occur when transferring an entity from one model to another. Figure 4 shows an illustrative example of the problem of entity transfer where an entity *e1* leaves activity *A1* in model *M1* at *T1* and arrives at queue *Q2* in model *M2* at *T2*. For example, if *M1* is a car production line and *M2* is a paint shop, then this represents the system where a car leaves a finishing activity in *M1* at *T1* and arrives in a buffer in *M2* at *T2* to await painting.

IRM Type A Subtypes

There are currently three IRM Type A subtypes:

- IRM Type A.1: general entity transfer
- IRM Type A.2: bounded receiving element
- IRM Type A.3: multiple input prioritization.

IRM Type A.1: General Entity Transfer

IRM Type A.1, general entity transfer, represents the case, as described above and shown in Fig. 4, where an entity *e1* leaves activity *A1* in model *M1* at *T1* and arrives at queue *Q2* in model *M2* at *T2* (see above for an example). This IRM is inclusive of cases where

- there are many models and many entity transfers (all transfers are instances of this IRM).

This IRM does not include cases where

- the receiving element is bounded (IRM Type A.2), and
- multiple inputs need to be prioritized (IRM Type A.3).

The IRM Type A.1, general entity transfer, is defined as the transfer of entities from one model to another such that an entity *e1* leaves model *M1* at *T1* from a given place and arrives at model *M2* at *T2* at a given place and $T1 \leq T2$ or $T1 < T2$. The place of departure and arrival will be a queue, workstation, etc. Note that this inequality must be specified.

IRM Type A.2: Bounded Receiving Element

Consider a production line where a machine is just finishing working on a part. If the next element in the production process is a buffer in another model, the part will be transferred from the machine to the buffer. If, however, the next element is *bounded*, for example a buffer with limited space or another machine (i.e., no buffer space), then a check must be performed to see if there is space or the next machine is free. If there is no space, or the

Figure 4. IRM Type A.1: general entity transfer.

next machine is busy, then to correctly simulate the behavior of the production process, the current machine must hold onto the part and *block*, that is, it cannot accept any new parts to process until it becomes unblocked (assuming that the machine can only process one part at a time). The consequences of this are quite subtle. This is the core problem of the IRM Type A.2. Figure 5 shows an illustrative example where an entity e_1 attempts to leave model M1 at T1 from activity A1 and to arrive at model M2 at T2 in bounded queue Q2. If A1 represents a machine, then the following scenario is possible. When A1 finishes work on a part (an entity), it attempts to pass the part to queue Q2. If Q2 has spare capacity, then the part can be transferred. However, if Q2 is full, then A1 cannot release its part and must block. Parts in Q1 must now wait for A1 to become free before they can be machined. Further, when Q2 once again has space, A1 must be notified so that it can release its part and transfer it to Q2. Finally, it is important to note the fact that if A1 is blocked the rest of model M1 still functions as normal, that is, a correct solution to this problem must still allow the rest of the model

to be simulated (rather than just stopping the simulation of M1 until Q2 has unblocked).

This IRM is therefore inclusive of cases where

- the receiving element (queue, workstation, and so on) is bounded.

This IRM does not include cases where

- multiple inputs need to be prioritized (IRM Type A.3).

A solution to this IRM problem must also

- be able to transfer entities (IRM Type A.1).

The IRM Type A.2 is defined as the relationship between an element O in a model M1 and a bounded element Ob in a model M2 such that if an entity e is ready to leave element O at T1 and attempts to arrive at bounded element Ob at T2, then

- if bounded element Ob is empty, the entity e can leave element O at T1 and arrive at Ob at T2; or

Figure 5. IRM Type A.2: bounded receiving element.

- if bounded element Ob is full, the entity e cannot leave element O at T1; element O may then block if appropriate and must not accept any more entities;
- when bounded element Ob becomes not full at T3, entity e must leave O at T3 and arrive at Ob at T4; element O becomes unblocked and may receive new entities at T3;
- $T1 \leq T2$ and $T3 \leq T4$;
- if element O is blocked, then the simulation of model M1 must continue.

Note:

- In some special cases, element O may represent some real-world process that may not need to be blocked.
- If $T3 < T4$, then it may be possible for bounded element O to become full again during the interval if other inputs to Ob are allowed.

IRM Type A.3: Multiple Input Prioritization

As shown in Fig. 6, the IRM Type A.3, multiple input prioritization, represents the case where a model element such as queue Q1 (or workstation) can receive entities from multiple places. Let us assume that there are two models M2 and M3 which are capable of sending entities to Q1 and that Q1 has a first in, first out (FIFO) queueing discipline. If an entity e1 is sent from M2 at T1 and arrives at Q1 at T2 and an entity e2 is sent from M3 at T3 and arrives at Q1 at T4, then if $T2 < T4$ we would expect the order of entities in Q1 would be e1, e2. A problem arises

when both entities arrive at the same time, that is, when $T2 = T4$. Depending on implementation, the order of entities would either be e1, e2 or e2, e1. In some modeling situations, it is possible to specify the *priority* order if such a conflict arises, for example, it can be specified that model M1 entities will always have a higher priority than model M2 (and therefore require the entity order e1, e2 if $T2 = T4$). Further, it is possible that this priority ordering could be dynamic or specialized.

This IRM is therefore inclusive of cases where

- multiple inputs need to be prioritized.

This IRM does not include cases where

- the receiving element is bounded (IRM Type A.2).

A solution to this IRM problem must also

- be able to transfer entities (IRM Type A.1).

The IRM Type A.3, multiple input prioritization, is defined as the preservation of the priority relationship between a set of models that can send entities to a model with receiving queue Q, such that priority ordering is observed if two or more entities arrive at the same time.

Note:

- The priority rules must be specified.
- Priority rules may change during a simulation if required for the real system being simulated.

Figure 6. IRM Type A.3: multiple input prioritization.

CASE STUDY

In Ref. 41, experiences with the use of discrete-event simulation to investigate the supply chain of blood from the UK National Blood Service (NBS) Centre to hospitals are described. The CSP used in this work was Simul8™. The purpose of the study was to achieve improved inventory control, ordering, and distribution policies; to bring less wastage and less shortage; and provide better quality service. This was done by reconfiguring the processes and parameters of the system. A problem identified in this work was that, as the system being modeled grew in size and complexity, the time taken to perform one simulation run increased to a point that made the use of simulation infeasible. Figure 7 shows a simplified illustration of this simulation model. For multiple hospitals, Fig. 8 shows an example of the relationships between the NBS supply center and the hospitals it serves, which in the “conventional” approach is simulated on a single computer.

Figure 9 shows the conventional model of Fig. 8 using our distributed approach. The natural “division” in the model is between the hospitals and the NBS Center. The NBS distributed simulation fits the profile of the Type A.1 IRM (entity transfer, $T1 < T2$), that is, dividing the model into federates results in individual, distributed models of the

Southampton NBS PTI and hospitals that interact by exchanging entities. There are no bounded buffers, and queueing discipline is not an issue. The condition $T1 < T2$ holds as entities will always take simulated time to transfer from one model to another (effectively travel time). These models run in separate copies of Simul8. Together, these form a federation that interact by time-stamped messages that represent the interaction of one model part with another (e.g., when an entity leaves one part of a model and arrives at another). Entities are represented using the CSPI entity transfer specification and exchanged using HLA interactions. In this investigation, the interaction between the models/Simul8 and the HLA-DMSO RTI is via an Excel file (as the main data used by each model is held in this file). For example, entities representing orders are written into the file by Simul8 during the execution of hospital models. The HLA-DMSO RTI, augmented by the CSPI standards, then correctly transfers this information to the NBS model by means of HLA interactions. The incoming orders from each hospital are collected into their corresponding queues in the NBS model and the orders are matched with the available stock of blood. The resulting matched units are written into the Excel spreadsheet in the NBS federate. This information is then

Figure 7. Simplified National Blood Service model.

Figure 8. National Blood Service conventional model.

Figure 9. National Blood Service distributed model.

sent to the different hospital models again through HLA interactions. The interactions between the hospitals and the NBS center are sent every 60 min of simulated time, provided orders/delivers exist. Thus, although the discrete-event simulation generates orders and deliveries as the model progresses in time, these are only released at specific time steps. It is to be noted here that this time-stepped information exchange behavior occurs as a result of the blood ordering and delivery policies in place with NBS. The distributed simulation successfully achieved a faster runtime than the standalone counterpart. Further details on this work and the implementation of the distributed simulation can be found in Refs 42 and 43.

FURTHER READING

This article has presented distributed simulation from an ORMS viewpoint. Distributed simulation is a complex area which in some ways is a realm for computer scientists. The case study briefly presented was the result of a close collaboration between ORMS researchers, computer scientists, and a CSP vendor. Previous experience such as this has resulted in the IRMs in this article as an accessible entry point to this fascinating field. It is hoped that this “re-presentation” of this field in terms of ORMS will make the highly useful technique of distributed simulation more available to ORMS practitioners and researchers. In terms of further reading,

readers should refer to the Winter Simulation Conference (www.wintersim.org), which has online, free-to-access papers on a variety of simulation-related topics. There are regular papers on distributed simulation and interoperability. Additionally, readers should also investigate how *Grid Computing* can speed up experimentation and optimization in ORMS in this area, as this is also proving to be another fruitful outcome from the interface between ORMS and computer science [44,45]. Related to this is the development of the SOHR, which is a runtime infrastructure based on Grid services [46]. Readers should also see the study performed in Ref. 47, which reflects on associated areas of simulation technology.

DOMINATION PROBLEMS

SIQIAN SHEN

Department of Industrial and
Systems Engineering,
University of Florida,
Gainesville, Florida

INTRODUCTION

Given a graph $G(V, E)$ with vertex set V and edge set E , we say that a vertex can “dominate” itself as well as all adjacent vertices. A *dominating set* S is a subset of V , such that every vertex in V is dominated by at least one vertex in S . Domination began as a problem on a chessboard [1], where we solve for a minimum number of queens that can be placed on a chessboard so that every square is either occupied by a queen, or can be occupied by one of the queens within a single move. A standard form of the domination seeks a dominating set with minimum cardinality [2,3].

Domination-related problems have received extensive attention after the 1970s because of their great importance in the usage of military, social network, medicine, and many other real-world problems. Over 1200 papers in areas of mathematics, computer science, and operations research have been published based on the study of domination and its related topics, such as independence and covering. See Refs 4 and 5 for a comprehensive discussion of theories and algorithms that have been studied regarding fundamentals and advanced topics of domination.

Notations and Definitions

We first introduce the notation that is commonly used in the domination literature. Assume that $G(V, E)$ is undirected, and let $|\cdot|$ be the cardinality of $(\cdot)$. The number of vertices, denoted as $|V| = n$, is the *order* of G , and the number of edges, denoted as $|E| = m$,

is the *size* of G . We specify the vertex set $V = \{v_1, \dots, v_n\}$ and edge set $E = \{e_1, \dots, e_2\}$. Denote $e = v_i v_j \in E$ as an undirected edge $\{v_i, v_j\} \in E, v_i, v_j \in V, v_i \neq v_j$. If $e = v_i v_j \in E$, we say that v_i and v_j are *adjacent*, and v_i (or v_j) and e are *incident*.

Let $N(v)$ be the *open neighborhood* of vertex $v \in V$, such that $N(v) = \{u \in V | vu \in E\}$, and $N[v] = N(v) \cup \{v\}$ is called the *closed neighborhood* of v . Similarly, for any subset $S \subseteq V$, the open and closed neighborhoods of S are denoted as $N(S)$ and $N[S]$, respectively, where $N(S) = \bigcup_{v \in S} N(v)$ and $N[S] = N(S) \cup S$. The *degree* of vertex v , denoted as $\deg(v)$, is calculated as the number of distinct vertices that are adjacent to v , that is, $\deg(v) = |N(v)|$. We describe the *degree sequence* of graph G as $\{\deg(v_1), \dots, \deg(v_n)\}$, typically in a nonincreasing or a nondecreasing order. We also use $\delta(G)$ and $\Delta(G)$ to denote the *minimum* and the *maximum degrees* of vertices in V , respectively.

For any pair of $u, v \in V$, the *distance* $d(u, v)$ is the shortest path length between u and v in G . In particular, if u and v are disconnected, we have $d(u, v) = +\infty$. We define *ecc*(v) as the *eccentricity* of v , such that $\text{ecc}(v) = \max\{d(v, u) | \forall u \in V\}$. Moreover, given $v \in V$ and $S \subseteq V$, we define the *distance* between v and S as $d(v, S) = \min_{u \in S} \{d(v, u)\}$, and the *eccentricity* of S is $\text{ecc}(S) = \max_{v \in V} \{d(v, S)\}$. For any graph G , we also define the *radius* $\text{rad}(G)$ and the *diameter* $\text{diam}(G)$ such that $\text{rad}(G) = \min_{v \in V} \{\text{ecc}(v)\}$, and $\text{diam}(G) = \max_{v \in V} \{\text{ecc}(v)\}$. By applying triangle inequality, the following result holds.

Theorem 1 [5]. For any connected graph G , $\text{rad}(G) \leq \text{diam}(G) \leq 2\text{rad}(G)$.

We illustrate the notation in Fig. 1, in which we present an unweighted and undirected graph with $n = 8$ vertices and $m = 9$ edges. The open neighborhood of vertex 3 is $N(3) = \{2, 4, 5\}$ with vertex degree $\deg(3) = 3$. The closed neighborhood $N[\{3, 5\}]$ is $\{2, 3, 4, 5, 6, 8\}$, and $d(2, 5)$ is 2. Moreover,

Figure 1. Illustration of notation and definitions.

$ecc(3) = \max\{d(3, u)\} = d(3, 7) = 3$, $rad(G) = \min_{v=1, \dots, 8} \{ecc(v)\} = ecc(3) = 3$, and $diam(G) = \max_{v=1, \dots, 8} \{ecc(v)\} = ecc(1) = ecc(7) = 5$. The minimum and maximum degrees of vertices are $\delta(G) = 2$ and $\Delta(G) = 3$, respectively.

Graph Variations

The characteristics of domination have been explored on graphs with different parameters. Next, we define all classes of graphs that we will use in our later discussion.

- *Split Graphs and Bipartite Graph.* A set S is a *stable set/independent set* if any pair of vertices in S is not adjacent. A set S is a *clique* if every pair of vertices is adjacent to each other. A graph is called a *split graph* if it can be partitioned into a stable set and a clique. A graph is called a *bipartite graph* if it can be partitioned into two stable sets.
- *Intersection Graph.* A graph $G(V, E)$ is called an *intersection graph* for a finite family $\mathcal{F}$ if there is a one-to-one correspondence between $\mathcal{F}$ and V such that two sets in $\mathcal{F}$ have nonempty intersection if and only if their corresponding vertices in V are adjacent. $\mathcal{F}$ is an *intersection model* of G .
 - *Interval Graph.* If $\mathcal{F}$ is given as a family of intervals on a real line, G is called an *interval graph*.
 - *Circular-Arc Graph.* If $\mathcal{F}$ is given as a family of arcs in a circle, G is called a *circular-arc graph*.
- *Chordal Graph.* A *perfect elimination order* is an ordering $V = \{v_1, \dots, v_n\}$ of G such that for every i, j , and k ($i < j < k$), if $v_i v_j \in E, v_i v_k \in E$, then $v_j v_k \in E$. A graph is *chordal* if and only if it admits a perfect elimination order, that is, every cycle of G of length greater than 3 has a “chord”—an edge between two nonconsecutive vertices in the cycle.
- *Strongly Chordal Graph.* A *strong elimination order* is a perfect elimination order satisfying for every i, j, k , and l ($i < j < k < l$) $:= v_i v_k \in E, v_i v_l \in E, v_j v_k \in E$, then $v_j v_l \in E$. A graph is *strongly chordal* if it admits a strong elimination ordering, that is, a chordal graph with every cycle of even length exceeding 5 has an odd chord. Strongly chordal graphs are important, including many interesting classes of graphs such as trees, block graphs, interval graphs, and directed path graphs.
- *Distance-Hereditary Graph.* A graph G is a *distance-hereditary graph* if every pair of vertices has the same distance in every connected induced subgraph containing them.
- *Series-Parallel Graph.* A *two-terminal graph* (TTG) $G(s, t)$ contains two distinguished nodes s and t , representing a *source* and a *sink*, respectively. Given two TTGs $G_1(s_1, t_1)$ and $G_2(s_2, t_2)$, a *series composition* creates a new TTG by merging the sink t_1 and the source s_2 , where s_1 becomes new source and t_2 becomes the new destination node. We define such a series operation by $G = S(G_1, G_2)$. A *parallel composition* creates a new TTG by merging the two sources s_1 and s_2 into the new source node, and the two sinks t_1 and t_2 into the new destination node. The parallel operation is denoted by $G = P(G_1, G_2)$. A *series-parallel graph* (SPG) is a graph that is constructed by a sequence of series and parallel compositions starting from a set of copies of a single edge graph.
- *Directed and Undirected Path Graph.* A *directed path graph* is a directed graph with no directed cycles. *Undirected path graphs* are the vertex intersection graphs of paths in a tree.
- *Permutation Graph.* A *permutation graph* is the intersection graph of a

family of line segments that connect two parallel lines in the Euclidean plane. Equivalently, given a permutation $(\pi_1, \dots, \pi_n)$ of $\{1, \dots, n\}$, a permutation graph has a vertex for each number $1, \dots, n$, and an edge between any two numbers that are in reversed order in the permutation.

The remainder of the paper is organized as follows. In the section titled “The Dominating Set Problem,” we formally state the dominating set problem. We review the algorithmic complexity of domination and domination-related parameters of graphs, and provide some solving strategies. The section titled “The Domination Chain” relates domination with independence and irredundance, and shows properties of the domination chain and its parameters’ complexity. In the section titled “Variants of Domination,” we list variants of domination in graphs, and describe the corresponding bounds and complexity details. The section titled “Applications” states several domination-related applications. Finally, the section titled “Summary and Open Questions” concludes the article and provides some open problems that are remaining in domination for potential future research.

THE DOMINATING SET PROBLEM

Originating from the queens problem, the dominating set problem and many of its variants have been introduced to solve varied practical problems. A general standard form of a dominating set problem is defined by

Definition 1. Given $G(V, E)$, a subset $S \subseteq V$ is called a *dominating set* if every vertex $v \in V$ is either an element of S or adjacent to at least one element of S .

Haynes *et al.* [5] summarize the following equivalent definitions, each of which defines the dominating set problem. A subset $S \subseteq V$ is a dominating set if one of the following is true:

1. $\forall v \in V - S$, there exists $u \in S$ such that $uv \in E$;
2. $\forall v \in V - S$, $d(v, S) \leq 1$;

3. $N[S] = V$;
4. $\forall v \in V - S$, $N(v) \cap S \neq \emptyset$.

Note that if $S \subseteq V$ is a dominating set, any superset of S is also a dominating set. This motivates us to find the *minimal dominating set* S of G , such that no proper subset $S' \subset S$ is a dominating set. To verify whether a given set S is a minimal dominating set, we introduce the definitions of *enclave* and *isolate*, such that

Definition 2. A vertex $v \in S$ is called an *enclave* of S if $N[v] \subseteq S$, and $v \in S$ is an *isolate* if $N(v) \subseteq V - S$.

Ore [3] gives the detailed proof of the following first three theorems for the dominating set problem.

Theorem 2 [3]. A dominating set S is minimal if and only if one of the following two conditions hold for every vertex $u \in S$:

- u is an isolate of S ;
- there exists a vertex $v \in V - S$, such that $N(v) \cap S = \{u\}$.

Theorem 3 [3]. Every connected graph G of order $n \geq 2$ has a dominating set S whose complement set $V - S$ is also a dominating set.

Theorem 4 [3]. If G has no isolated vertices, then for every minimal dominating set S , the complement set $V - S$ is also a dominating set.

Cockayne and Hedetniemi [6] are the first to introduce the concept of domination number, denoted as $\gamma(G)$, and $\gamma(G)$ and $\Gamma(G)$ denote the minimum and the maximum cardinality of a minimal dominating set in G , respectively. A minimum dominating set is also called a γ -set. Letting $\epsilon_F(G)$ to be the maximum number of pendant (leaf) edges in a spanning forest of G , we present the following basic theorem.

Theorem 5 [7]. $\gamma(G) + \epsilon_F(G) = n$.

We illustrate the difference between concepts of the *minimal* and the *minimum*

Figure 2. Illustration of minimal and minimum dominating sets.

in Fig. 2, in which both solutions (i.e., the marked subsets of vertices) provide us minimal dominating sets, since the deletion of any vertex will lead to a non-dominated graph. However, the solution in the bottom (the lightly marked one) also gives a minimum dominating set, that is, $\gamma(G) = 3$.

Finding the minimum dominating set in a graph G then becomes one of the standard combinatorial problems that is substantially interesting. A decision version of this problem is stated as “does G have a dominating set of size $\leq k$ for any given positive integer k ?” It has been shown that this problem, called *DOMINATING SET*, is $\mathcal{NP}$ -complete in general graphs, derived from a transformation of 3-SAT [8]. Moreover, the study of *DOMINATING SET* has been extended to problems with modified domination-related statements, or given varied parameters of graphs. In some cases, it is possible to obtain polynomial algorithms. The complexity and algorithm details with respect to each domination-related problem are discussed throughout the remainder of the article.

Bounds for the Domination Number $\gamma(G)$

Since the dominating set problem is $\mathcal{NP}$ -complete for general graphs, many studies seek good-quality bounds for $\gamma(G)$. This problem is tackled from different angles such as in terms of number of vertices, number of edges, degree, and diameter. We briefly review some

of the related results that have been proposed during the past two decades. Note that they are not comprehensive, and only represent a part of the literature.

It is trivial to see that $1 \leq \gamma(G) \leq n$, in which $\gamma(G)$ reaches the lower bound if there exists at least one vertex $v \in V$ such that $\deg(v) = n - 1$, and $\gamma(G)$ achieves the upper bound if all vertices are isolated. Recall that $\delta(G)$ is the minimum degree of vertices in V . If $\delta(G) \geq 1$, that is, no isolated vertex exists in G , we have a direct result in the following:

Theorem 6 [3]. *If G has no isolated vertices such that $\delta(G) \geq 1$, then $\gamma(G) \leq \lfloor n/2 \rfloor$.*

Then, an intuitive question arises as to whether we can tighten the upper bound for $\gamma(G)$ when $\delta(G)$ increases. We show some representative results as follows:

Theorem 7 [9]. *If G is a connected graph with $\delta(G) \geq 3$, then $\gamma(G) \leq \lfloor 3n/8 \rfloor$.*

Theorem 8 [10,11]. *For any graph G with $\delta(G) \geq 7$, we have $\gamma(G) \leq n \left[1 - \delta(G) \left(\frac{1}{\delta(G)+1} \right)^{1+1/\delta} \right]$.*

However, for graph G with $4 \leq \delta(G) \leq 6$, the question is still open [5]. The following theorem calculates bounds for $\gamma(G)$ for almost every graph.

Theorem 9 [12]. *For almost every order- n graph, let $k = \lfloor (\log n - 2 \log \log n + \log \log e) \rfloor$. We have $k + 1 \leq \gamma(G) \leq k + 2$.*

In terms of n and $\Delta(G)$, to obtain a lower and an upper bound for $\gamma(G)$, a trivial result is shown as follows:

Theorem 10 [2,13]. *For any graph G , $\left\lceil \frac{n}{1+\Delta(G)} \right\rceil \leq \gamma(G) \leq n - \Delta(G)$.*

The proof is intuitive, and here we generally describe the idea. For the lower bound, since each vertex can dominate itself and all its adjacent vertices, that is, at most $(1 + \Delta(G))$ vertices, we need at least $\left\lceil \frac{n}{1+\Delta(G)} \right\rceil$ vertices to dominate G . For the upper bound, a feasible dominating solution can be given as a set containing the maximum degree vertex (dominating itself and all its connections) and all other vertices (dominating themselves), and thus, $\gamma(G) \leq n - \Delta(G)$.

Moreover, considering a graph G with a *nonincreasing* degree sequence $(\deg(v_1), \dots, \deg(v_n)) = (d_1, \dots, d_n)$, a tighter lower bound can be given by

Theorem 11 [14]. $\gamma(G) \geq \min\{k : k + (d_1 + d_2 + \dots + d_k) \geq n\}$.

The proof is similar to finding the lower bound in Theorem 10. We sequentially include vertices from the degree sequence such that they dominate themselves as well as their adjacent vertices. We repeat this procedure until all the vertices in V are dominated, and Theorem 11 provides the smallest vertices that we need in the best case such that all the picked vertices are not adjacent to each other. Moreover, we refer readers to Refs 5,15, and 16 for varied upper bound results in terms of $\delta(G)$ and $\Delta(G)$.

Similarly, we give the following bounds for $\gamma(G)$ in terms of n and m .

Theorem 12 [17]. *If a graph G has $\gamma(G) \geq 2$, then $m \leq \lfloor \frac{1}{2}(n - \gamma(G))(n - \gamma(G) + 2) \rfloor$.*

Theorem 13 [18]. *If a graph G has $\gamma(G) \geq 2$ and $\Delta(G) \leq n - \gamma(G) - 1$, then $m \leq \frac{1}{2}(n - \gamma(G))(n - \gamma(G) + 1)$.*

Considering bounds for $\gamma(G)$ in terms of the degree and diameter, we give the following two elementary theorems:

Theorem 14 [5]. *Given a graph G with $\text{diam}(G) = 2$, we have $\gamma(G) \leq \delta(G)$, that is, $N(v)$ dominate G for any vertex $v \in V$.*

Theorem 15 [5]. *If G is a connected graph, we have $\left\lceil \frac{\text{diam}(G)+1}{3} \right\rceil \leq \gamma(G)$.*

Solving Domination Problems

Solving the domination problem on various types of graphs has stimulated great interests in studies of operations research, combinatorial optimization, and computer science. In this section, we particularly review optimization techniques to formulate the domination, such as integer programming (IP). We also examine a polynomial-time algorithm for solving the domination problem on trees.

Combinatorial Optimization and Integer Programming. Let x_i be a binary variable indicating whether vertex $i \in V$ is contained in a minimum dominating set S , such that $x_i = 1$ if $i \in S$, and $x_i = 0$ otherwise. We propose the following IP formulation:

$$\gamma(G) = \min \sum_{i \in V} x_i \quad (1a)$$

$$\text{s.t.} \quad \sum_{i \in N[v]} x_i \geq 1 \quad \forall v \in V \quad (1b)$$

$$x_i \in \{0, 1\} \quad \forall i \in V, \quad (1c)$$

where Equation (1c) causes main computational difficulty in solving Equation (1a). By relaxing $x \in [0, 1]^{|V|}$, a linear programming (LP) relaxation provides optimal solutions for a *fractional domination* problem [19], and a lower bound for the IP model [20]. An alternative approach can also be used to obtain a lower bound value as follows. We define $Y = xx^T$, which is a positive semi-definite (PSD) $|V| \times |V|$ matrix (i.e., $z^T Y z \geq 0$ holds for any vector $z \in \mathbb{R}^n$). Note that $y_{ii} = x_i^2 = x_i$ due to the binary values of x_i for all $i \in V$. We present a semi-definite programming (SDP) model as

$$\gamma(G) \geq \min tr(Y) \quad (2a)$$

$$\text{s.t. } \sum_{i \in N[v]} y_{ii} \geq 1 \quad \forall v \in V \quad (2b)$$

$$Y \succeq 0, \quad (2c)$$

where $tr(Y)$ is the trace of Y , that is, the sum of all diagonal values of matrix Y , and $Y \succeq 0$ denotes that Y is PSD. One can employ general-purpose convex optimization methods for solving Equation (1b).

Complexity of Domination-Related Parameters of Graphs and Algorithms. Recall that DOMINATING SET is $\mathcal{NP}$ -complete for an arbitrary graph, and $\mathcal{NP}$ -complete for bipartite graphs [21,22] (based on a transformation from DOMINATING SET), and chordal graphs (based on a transformation from EXACT COVER BY 3-SETS [8]). However, it is shown to be in the class $\mathcal{P}$ on trees, interval graphs, directed path graphs, and permutation graphs. In particular, we briefly describe a polynomial *labeling* algorithm for solving TREE DOMINATION [23] on an example as follows:

For a tree $T(V, E)$, we define three types of subsets of V as V_1 , V_2 , and V_3 that consist of *free*, *bound*, and *required* vertices, respectively, such that all the “required” vertices are contained in *any* optimal dominating set S of T . Every “bound” vertex in V_2 is dominated by V_3 , and it is either an element of S or is adjacent to at least one vertex in S . “Free” vertices in V_1 need not be dominated, or need not be in S , but still can be used in S to dominate some bound vertices. We require $V = V_1 \cup V_2 \cup V_3$. To compute the domination number $\gamma(T)$, we seek a partition $V = V_1 \cup V_2 \cup V_3$ associated with an optimal domination through a labeling process. The following observations lead to a polynomial algorithm for solving the domination for trees.

Theorem 16 [24]. *Given a tree T whose vertices are labeled “free” (V_1), “bound” (V_2), and “required” (V_3). Let v be an end-vertex of T that is adjacent to a vertex u , and $T - v$ is the tree obtained by deleting v from T . We have*

1. if $v \in V_1$, then $\gamma(T) = \gamma(T - v)$;
2. if $v \in V_2$ and T' is the tree obtained by relabeling u as “required” in $T - v$, then $\gamma(T) = \gamma(T')$;
3. if $v \in V_3$ and $u \in V_3$, then $\gamma(T) = 1 + \gamma(T - v)$;
4. if $v \in V_3$ and $u \notin V_3$, and T' is the tree obtained by relabeling u as “free” in $T - v$, then $\gamma(T) = 1 + \gamma(T')$.

Now, we root T at an arbitrary vertex, say vertex 1, and for every other vertex $t \in T$, we define $P[t]$ as the parent vertex of t ($P[1] = 0$ since the root vertex then has no parent vertex). Without presenting a rigorous proof of the algorithm correctness and complexity (for which we refer the interested readers to Refs 24 and 5), a solution scheme that solves the minimum cardinality dominating set S of T in $O(n)$ time is

1. Label all vertices $1, \dots, N$ “bound.”
2. For decreasing sequence of vertices $t = N, \dots, 2$, check the following cases: (i) if t is “bound”, label $P(t)$ as “required”; (ii) if t is “required” and $P(t)$ is “bound”, then $S = S \cup \{t\}$, and change $P(t)$ ’s label to “free”; (iii) if t is “required” and $P(t)$ is not labeled “bound,” then only update $S = S \cup \{t\}$.
3. Finally, check root vertex 1. If it is labeled “bound” or “required,” then update $S = S \cup \{1\}$; else, vertex 1 is not included in the dominating set S .

THE DOMINATION CHAIN

Since its first appearance in Ref. 25 in 1978, the domination chain has become a motivation for many studies of the domination and its variants. It reflects the relationship between domination, independence, and irredundance in graphs. We start this section by introducing two concepts regarding an arbitrary property of a general set, that is, *hereditary* and *superhereditary*. We say that a property P of set S is hereditary if every proper subset $S' \subset S$ also has P ; on the other hand, P is superhereditary if every proper superset $S'' \supset S$ has this property. For instance, being a dominating set is superhereditary.

Moreover, we say that a set S is a P -set if P holds for S . A P -set is a *maximal* P -set or a *minimal* P -set if every proper superset $S'' \supset S$ or every proper subset $S' \subset S$ does not have the property P , respectively. Thus, for all hereditary properties P , we are interested in finding the related maximal P -set, and for all superhereditary properties P , the results of minimal P -set are more favorable.

Next, we introduce the definitions of independent and irredundant sets, and explore the relations between the dominating set and the two sets, leading to a fruitful discussion of the domination chain.

Independent Sets and Irredundant Sets

Recall that given $G(V, E)$, a set $S \subset V$ is *independent* if no pair of vertices in S is adjacent. $\beta_0(G)$ is called the *independence number*, which is the maximum cardinality of an independent set in G . In Fig. 2, note that the γ -set (the second minimal dominating set) is an independent set, and we call it an *independent dominating set* of G . The *independent domination number* $i(G)$ is the minimum cardinality of an independent dominating set of G .

Note that being independent is a hereditary property, and thus we are interested in finding maximal independent sets in a graph G . An independent set S is maximal if and only if for all vertices $u \in V - S$, there exists a vertex $v \in S$ such that $uv \in E$. Note that this condition is exactly the definition of a dominating set. Thus, we have

Proposition 1 [2]. *A set S is a maximal independent set if and only if it is independent and dominating.*

Therefore, $i(G)$ also represents the minimum cardinality of a maximal independent set of G . Furthermore, we have

Proposition 2 [2]. *For any graph G , every maximal independent set is a minimal dominating set.*

Recall that $\gamma(G)$ is the minimum cardinality of a dominating set, and $\Gamma(G)$ is the maximum cardinality of a minimal dominating set. According to Propositions 1 and 2, we

describe a part of the domination chain as $\gamma(G) \leq i(G) \leq \beta_0(G) \leq \Gamma(G)$.

Before starting the discussion of the irredundant set, we define the private neighbor set of vertex $v \in S$ as $pn[v, S] = N[v] - N[S - \{v\}]$, that is, all vertices that are *only* adjacent to v but not any other vertex in S . The private neighbor set of S is then the collection of vertices in S that have nonempty private neighbor set, that is, $pn[S] = \{v : pn[v, S] \neq \emptyset\}$. A set S is *irredundant* if for every vertex $v \in S$ such that $pn[v, S] \neq \emptyset$, that is, every vertex in S is adjacent to at least one vertex that other vertices in S cannot reach.

Next, we consider the superhereditary property of being dominating, and focus on the minimal dominating sets. A dominating set of S is minimal if and only if for all vertices $v \in S$, $pn[v, S] \neq \emptyset$. Otherwise, we can exclude v from S , and are still able to dominate G . This condition is exactly the definition of an irredundant set, and similarly, the following two propositions hold.

Proposition 3 [25]. *A set S is a minimal dominating set if and only if it is dominating and irredundant.*

Proposition 4 [26]. *For any graph G , every minimal dominating set is a maximal irredundant set of G .*

Let $ir(G)$ denote the minimum cardinality of a maximal irredundant set, and $IR(G)$ be the maximum cardinality of a maximal irredundant set. Here comes the famous inequality as the domination chain:

Theorem 17 [25]. *For any graph G ,*

$$ir(G) \leq \gamma(G) \leq i(G) \leq \beta_0(G) \leq \Gamma(G) \leq IR(G). \quad (3)$$

Properties of the Domination Chain

Some interesting questions arise regarding Theorem 17, including (i) when do the inequalities in Equation (3) hold as equalities? (ii) Does any other similar inequality chain hold like Equation (3)? (iii) Given a graph G , what is a valid assignment for

Figure 3. Illustration of H graph and A-L graph.

values of parameters in Equation (3)? Next, we answer the three questions by reviewing some elementary results in literature.

Regarding question (i), two examples of graph G have been created to illustrate the cases when $ir(G) < \gamma(G)$, denoted as H [27] and A-L [28] in Fig. 3, respectively.

Theorem 18 [29]. *If G is a chordal graph containing no H or A-L as subgraphs, then $ir(G) = \gamma(G)$.*

Haynes *et al.* [5] also review many other conditions under which $ir(G) = \gamma(G)$. Moreover, considering $\beta_0(G)$, $\Gamma(G)$, and $IR(G)$, similar results can be derived as

Theorem 19 [30]. *If G is a bipartite graph, a chordal graph, or a graph that has no isolated vertices and $\gamma(G) + IR(G) = n$, then $\beta_0(G) = \Gamma(G) = IR(G)$.*

Next, regarding question (ii), consider one variant as the *edge* domination, independence, and irredundance. $F \subseteq E$ is called an *independent edge set* if no two edges in F share a common vertex. $\beta_1(F)$ and $i'(F)$ denote the maximum and minimum cardinality of maximal independent edge sets, respectively. Also, $F \subseteq E$ is a *dominating set* if all vertices in V are incident to at least one edge in F , and $\gamma'(F)$ and $\Gamma'(F)$ are the minimum and maximum cardinality of minimal dominating edge sets, respectively. Lastly, $F \subseteq E$ is an *irredundant set* if every edge in F has a

private neighbor edge, and $ir'(G)$ and $IR'(G)$ are the minimum and maximum cardinality of maximal irredundant sets. Haynes *et al.* [5] conclude that the same inequality chain holds for all the foregoing parameters.

Theorem 20 [5]. *For any graph G ,*

$$ir'(G) \leq \gamma'(G) \leq i'(G) \leq \beta_1(G) \leq \Gamma'(G) \leq IR'(G). \quad (4)$$

In particular, we have $\gamma'(G) = i'(G)$ for any graph G according to Ref. 28. Finally, considering question (iii), the following result considers the parameter validity of Equation (3).

Theorem 21 [31]. *For any graph G ,*

1. $ir(G) = 1$ implies $\gamma(G) = 1$ and $i(G) = 1$;
2. $\beta_0(G) = 1$ implies $\Gamma(G) = 1$ and $IR(G) = 1$;
3. $\gamma(G) \leq 2ir(G) - 1$.

We refer the interested readers to Ref. 5 for a thorough discussion on other variants of the domination chain and the corresponding results in terms of graph parameters.

Complexity of Parameters of the Domination Chain

Recall that the DOMINATING SET, that is, finding the domination number $\gamma(G)$, is $\mathcal{NP}$ -complete as stated in the section

titled “The Dominating Set Problem.” This section reviews the algorithmic complexity of computing other parameters in the domination chain. First, finding the irredundance number $ir(G)$ (IRREDUNDANT SET) on general graphs is $\mathcal{NP}$ -complete [32], and this result remains true on chordal graphs. However, it is polynomial solvable on any tree structure [33]. Moreover, Garey and Johnson [8] become the first to show that finding the independent domination number $i(G)$ (INDEPENDENT DOMINATING SET) is $\mathcal{NP}$ -complete on general graphs, and even on bipartite graphs [34] or in an edge domination version [35]. Farber [36] provides polynomial algorithms for both domination and independent domination on strongly chordal graphs.

Moreover, although finding the independence number $\beta_0(G)$ (INDEPENDENT SET) belongs to $\mathcal{NP}$ -completeness on general graphs [8], it can be solved in polynomial time when restricted to bipartite graphs, or chordal graphs [5]. Owing to Theorem 19, finding the upper domination number $\Gamma(G)$ and the upper irredundance number $IR(G)$ are also polynomially solvable on bipartite graphs and chordal graphs, but remain $\mathcal{NP}$ -complete on general graphs.

To emphasize, all parameters of Equation (3) are obtainable in polynomial time on trees. Recall that Ref. 24 is the first to give an $O(n)$ algorithm for solving $\gamma(T)$. We refer readers to Refs 33, 37, and 38 for the first linear algorithms for solving $ir(T)$, $i(T)$, and $\beta_0(T)$, respectively. Finally, owing to Theorem 19, $\Gamma(T)$ and $IR(T)$ are then polynomially solvable on trees as well [38].

VARIANTS OF DOMINATION

To solve practical real-world problems, we design domination-related problems by combining domination with another graph property P . For instance, we require domination along with independence or irredundance, of which we discuss the results in the last section. Some other interesting properties are naturally imposed on the dominating set S , including that S (i) has no isolated vertices, (ii) is connected, (iii) includes a complete graph, (iv) forms a perfect matching, and so on. More conditions can also be imposed on

the dominated set $V - S$, or on the dominating method, including multiple domination, strong and weak domination, and so on. Next, we discuss details of the domination with certain graph properties.

Total Dominating Set

Recall that $S \subseteq V$ being a dominating set is equivalent to $N[S] = V$. In some applications, we might be interested in those dominating sets that all elements in S are adjacent to at least one of the other elements in S , that is, no vertex in S is an isolate of S . We define it as a *total dominating set* of V if $N(S) = V$, and the total dominating set of G with the minimum cardinality is denoted as a γ_t -set.

Define the *boundary* of S as $B(S) = \{v \in S : |N[v] \cap S| = 1\}$, and the *open boundary* of S is $OB(S) = \{v \in S : |N(v) \cap S| = 1\}$. The minimal total dominating set can be characterized by

Theorem 22 [5]. *A dominating set S is minimal if and only if $B(S)$ dominates S . Similarly, a total dominating set S is minimal if and only if $OB(S)$ dominates S .*

We propose the following bounds for the total domination number $\gamma_t(G)$.

Theorem 23 [39]. *If G is a connected graph with $n \geq 3$, then $\gamma_t(G) \leq 2n/3$.*

Theorem 24 [39]. *If a graph G has no isolated vertices, then $\gamma_t(G) \leq n - \Delta(G) + 1$. If a graph G is connected and $\Delta(G) < n - 1$, then $\gamma_t(G) \leq n - \Delta(G)$.*

TOTAL DOMINATING SET is $\mathcal{NP}$ -complete on general graphs [40], bipartite graphs [40], and undirected graphs [41]. But it is in the class $\mathcal{P}$ on trees [41], interval graphs [42], and distance-hereditary graphs [43].

Connected Dominating Set

Sampathkumar and Walikar [44] first define a *connected dominating set* S , such that all elements in S are connected. $\gamma_c(G)$ is called the *connected domination number*. It is trivial to see that only connected graphs have a

connected dominating set, and the connected dominating set is a special case of the total dominating set. Thus, $\gamma(G) \leq \gamma_t(G) \leq \gamma_c(G)$ for any connected graph G with $\Delta(G) < n - 1$. According to Theorem 5, we give an upper bound for determining $\gamma_c(G)$ as follows:

Theorem 25 *If G is connected and $n \geq 3$, then $\gamma_c(G) = n - \epsilon_F(G) \leq n - 2$.*

Let $l(T)$ be the number of end-vertices of a tree T . The following corollary is straightforward according to Theorem 24.

Corollary 1 [44]. *If T is a tree with $n > 3$, $\gamma_c(T) = n - l(T)$.*

We propose several upper bounds in terms of the minimum and the maximum degrees $\delta(G)$ and $\Delta(G)$ as follows:

Theorem 26 [44,45]. *For any connected graph G , we have*

1. *if $\delta(G) \geq 3$, then $\gamma_c(G) \leq 3n/4 - 2$;*
2. *if $\delta(G) \geq 4$, then $\gamma_c(G) \leq 3n/5 - 2$;*
3. *$n/(\Delta(G) + 1) \leq \gamma_c(G) \leq 2m - n$, and equality is achieved at the lower bound if and only if $\Delta(G) = n - 1$, and is achieved at the upper bound if and only if G is a path;*
4. *$\gamma_c(G) \leq n - \Delta(G)$.*

Now considering $\gamma(G) \leq \gamma_t(G) \leq \gamma_c(G)$, the following theorem provides one scenario in which the equality is achieved.

Theorem 27 [46]. *If G is the complement of a bipartite graph or a split graph, we have $ir(G) = \gamma(G) = \gamma_t(G) = \gamma_c(G)$.*

A further variation of the connected dominating set is *weakly connected domination*, that is, for a dominating set S , the subgraph $G[S]_w = (N[S], E_w)$ weakly induced by S is connected, where E_w is the set of all edges with at least one incident vertex in S . Recent results of bounds for $\gamma_w(G)$ can be found in Refs 47 and 48. Swaminathan [48] also states necessary and sufficient conditions for

a graph G to have unique minimal weakly connected dominating set.

Finally, we review the algorithmic complexity of CONNECTED DOMINATING SET as follows. It has been shown in the class of $\mathcal{NP}$ -Complete on general graphs [32], bipartite graphs [32], and split graphs (and thus chordal graphs) [46], but in the class of $\mathcal{P}$ for distance-hereditary graphs [49]. It has very close relations with *Steiner tree* problem, and is thus $\mathcal{NP}$ -complete on many graphs. We refer readers to Ref. 50 for a linear-time algorithm for solving a minimum weighted connected dominating set and a minimum vertex-weighted Steiner tree problem on distance-hereditary graphs.

Dominating Cliques

A dominating set is called a *dominating clique* if all vertices of a dominating set S form a complete graph (i.e., every vertex is adjacent to every other vertex in S). The domination clique number is denoted by $\gamma_{cl}(G)$. Since a clique is a special case of connected graphs, we have

$$\gamma(G) \leq \gamma_t(G) \leq \gamma_c(G) \leq \gamma_{cl}(G). \quad (5)$$

In particular, if $\gamma(G) = 1$, then $\gamma_t(G) = \gamma_c(G) = \gamma_{cl}(G) = 1$. Also, the results of $\gamma_{cl}(G)$ are interesting mostly for chordal graphs. Kratsch *et al.* [51] characterize the chordal graphs that have dominating cliques.

Theorem 28 [51]. *Given a chordal graph G , it has a dominating clique if and only if $\text{diam}(G) \leq 3$.*

Theorem 29 [51]. *Given a strongly chordal graph G that has a dominating clique, we have*

1. $\gamma(G) = \gamma_{cl}(G)$;
2. $\gamma(G) = \gamma_t(G) = \gamma_c(G) = \gamma_{cl}(G)$, if $\gamma(G) \geq 2$.

The dominating clique problem is $\mathcal{NP}$ -complete on general graphs, but can be solved in polynomial time on strongly chordal graphs and undirected path graphs [52].

Paired-Dominating Sets

Another type of the domination is defined for the presence of perfect matching. A *paired-dominating set* is a dominating set S such that its induced subgraph has a perfect matching. From a practical perspective, the paired-domination is applicable and important for the following case [53]. Given a graph G , we need to assign guards to protect all vertices. The locations of all guards form a dominating set. If a total dominating set is required, each guard should be protected by at least one of other guards. In a paired-dominating set, we even further require each guard protected by his/her exclusive partner, and vice versa. Hence, the paired-dominating set is a special case of the total dominating set, and we have $\gamma(G) \leq \gamma_t(G) \leq \gamma_p(G)$ where $\gamma_p(G)$ is the paired-domination number. Moreover, we state the following two representative bounds for $\gamma_p(G)$.

Theorem 30 [53]. *For any G having no isolated vertices, $\gamma_p(G) \geq n/\Delta(G)$.*

Theorem 31 [53]. *For any G having no isolated vertices, $\gamma_p(G) \leq 2\gamma(G)$; if $\gamma_p(G) = 2\gamma(G)$, then every γ -set is an i -set.*

The paired-domination problem is $\mathcal{NP}$ -complete on general graphs [53]. Qiao *et al.* [54] describe a linear algorithm for solving paired-domination on tree structures. Polynomial algorithms have also been given on interval graphs, circular-arc graphs [55], and permutation graphs [56].

Multiple Domination

The following sections focus on varied dominations in terms of dominating methods. First, we are interested in *multiple domination* such that given a dominating set S , each vertex in $V - S$ is dominated by at least k vertices in S where k is a given positive integer. The concept was first introduced in Ref. 57, to support the idea of network robustness. That is, deleting a vertex in a normal dominating set might lead to a non-dominated case, while a vertex failure in a multiple domination would still be tolerable for dominating the graph afterward. We

denote the *k-domination number* $\gamma_k(G)$ as the minimum cardinality of an *k-dominating set*, such that every vertex in $V - S$ is dominated by at least k vertices in S . Note that $\gamma_1(G) = \gamma(G)$, and for $1 \leq i \leq j$, if S is a j -dominating set, it is also an i -dominating set, and thus $\gamma_i(G) \leq \gamma_j(G)$.

Before further exploring relations between $\gamma_k(G)$ and $\gamma(G)$, we present the following observation.

Theorem 32 [57]. *Given a γ -set S of G , at least one vertex in $V - S$ is dominated by no more than two vertices in S .*

According to this, if $\Delta(G) \geq 3$ and $k \geq 3$, no k -dominating set for G can be a minimum dominating set, and the following strict inequality holds

Theorem 33 [57]. *If G is a graph with $\Delta(G) \geq 3$ and $k \geq 3$, then $\gamma(G) < \gamma_k(G)$.*

A further variant is the *k-tuple dominating set*, which is obtained by modifying the definition of k -domination. A set S is *k-tuple dominating set* if each vertex in V is dominated by at least k vertices in S , which is different from the requirement by k -domination where only every vertex in $V - S$ needs to be dominated by at least k vertices in S . $\gamma_{\times k}(G)$ is the k -tuple domination number. It follows the definitions that, for any graph G

$$\begin{aligned} \gamma(G) &\leq \gamma_k(G) \leq \gamma_{\times k}(G) \text{ and} \\ \gamma(G) &= \gamma_1(G) = \gamma_{\times 1}(G). \end{aligned} \quad (6)$$

A special case of k -tuple domination is *double domination* when $k = 2$, which has been shown in the class of $\mathcal{P}$ on trees [58]. Liao and Chang [59] further provide a polynomial algorithm for solving the k -tuple domination on strongly chordal graphs, and show that the problem remains $\mathcal{NP}$ -complete on split and bipartite graphs.

Strong and Weak Domination

In 1996, Sampathkumar and Latha [60] first introduced the concepts of strong and weak domination. Given two adjacent vertices u and v , we say that u *strongly dominates* v if

$\deg(u) \geq \deg(v)$, and u weakly dominates v if $\deg(u) \leq \deg(v)$. A set $S \subseteq V$ is a *strong dominating set/weak dominating set* if every vertex in $V - S$ is strongly/weakly dominated by at least one vertex in S . $\gamma_S(G)$ and $\gamma_W(G)$ are the *strong domination number* and *weak domination number*, respectively. Since either strong or weak dominating set is a special case of the dominating set, $\gamma(G) \leq \gamma_S(G)$ and $\gamma(G) \leq \gamma_W(G)$, but no inequality relation can be drawn between $\gamma_S(G)$ and $\gamma_W(G)$. Letting $\bar{G}$ to be the complement graph of G , we propose the strong and weak domination properties in terms of the graph degrees as follows:

Theorem 34 [60]. *For any graph G , the following inequalities hold*

1. $\gamma(G) \leq \gamma_S(G) \leq n - \Delta(G)$;
2. $\gamma(G) \leq \gamma_W(G) \leq n\delta(G)$;
3. $\gamma_S(\bar{G}) + \gamma_W(G) \leq n + 1$.

However, no inequality relation can be drawn between $\gamma_S(G)$, $\gamma_W(G)$ and $i(G)$, $\gamma_c(G)$, and $\alpha_0(G)$ [60]. Last, both STRONG and WEAK DOMINATING SET problems are $\mathcal{NP}$ -complete on general graphs, and even on bipartite graphs. But they are in the class $\mathcal{P}$ when applied to trees [5], and the labeling algorithm is again employed to solve the problem.

In addition to all domination-related problems previously mentioned, we refer readers to Ref. 5 for more variants, including *dominating cycles*, *restrained domination*, *locating domination*, *distance domination*, *directed graph domination*, and so on. Also, some new domination variants have recently been introduced because of their convenience for describing practical problems, for example, domination with exponential decay [61] and rainbow domination [62]. The rainbow domination is $\mathcal{NP}$ -complete on most graphs, including bipartite and split graphs. In a very recent paper, Chang *et al.* [63] provide a polynomial-time algorithm for solving the rainbow domination on tree structures.

APPLICATIONS

The domination has received substantially large attention in the past three decades due

to its wide usage in real-world applications. We next review its variants that serve as theoretical fundamentals for several practical problems.

Domination in Wireless Ad hoc Networks and Approximation Algorithms

A mobile ad hoc network is a wireless and infrastructureless communication network that contains a set of local sensors. A sensor receives data and sends them to others that are within the signal transmission range according to some routing protocols. Williams and Camp [64] comprehensively evaluate and compare performances of many protocols under different network conditions. In general, most protocols feature on-demand routing, and require flooding of route requests by using local broadcasts.

Ad hoc networking-related problems have drawn substantially great interests because of their importance in military, disaster relief, health care industry, social communications, and so on. However, these networks usually feature dynamic topology, resource limitation (e.g., battery and bandwidth), and a lack of infrastructure. Motivated by the broadcast storm problem [65] caused by flooding used in many routing protocols, as well as the broadcast unreliability issue [66], some wireless network construction papers have suggested the virtual backbone as an alternative to a fixed routing infrastructure, which is also a backup when route is temporarily unavailable [67,68].

The virtual backbone is a cluster placed at certain place in the network, and captures all local changes that happen within the range. As we also need to route messages between clusters, a connected dominating set (CDS) becomes a natural alternative to approximate virtual backbone infrastructure. In literature, a wireless network is usually characterized by a unit disk graph [69], consisting of a set of all identical sensors and a set of edges between paired sensors whose distance is within the communication range.

Computing CDS on a unit disk graph is $\mathcal{NP}$ -hard [70], and thus many works have been conducted on finding approximation algorithms with good performance [71,72]. Three types of algorithms exist

for solving CDS: centralized algorithms [73,74], constant-time (fast) localized distributed algorithms [75–77], and linear-time localized distributed algorithms [78,79], as summarized in Ref. 80. We review some representative works in each category as follows.

Guha and Khuller [74] propose two polynomial-time centralized algorithms that have approximation factors of $2H(\Delta) + 2$ and $H(\Delta) + 2$ from optimum, respectively, where H is a harmonic function and Δ is the maximum node degree. However, centralized algorithms are usually difficult to implement due to the hardness of collecting and maintaining the complete graph topology information. On the other hand, distributed localized algorithms analyze the CDS topology in a local neighborhood, and sequentially pass this information through each node in the network. Bharghavan and Das [81] cast the two centralized algorithms of Guha and Khuller [74] into distributed implementations, whose performance, however, is still restricted to the transmission messages' complexities. Wan *et al.* [79] provide a constant-time approximation for solving CDS in ad hoc networks; several other papers on this concept include Refs 70,82–84. They use a similar two-stage solution scheme that constructs a dominating set in the first phase, and connects it to a CDS in the second phase. Gandhi and Parthasarathy [80] propose two constant-time distributed algorithms that converge in $O(\log^2 n \Delta)$ and in $O(\log^2 n)$ times, respectively, where Δ again represents the maximum degree and n is the number of nodes in the network. To the best of our knowledge, they are the first fast localized distributed approximation algorithms for constructing CDS on wireless ad hoc networks considering loss of messages due to wireless interference. Tiwari *et al.* [85] study the problem on a 2D unit disk graph, as well as a 3D ball graph, and employ coloring methods to derive constant-time approximation algorithms for interference-aware broadcast scheduling in multihop wireless sensor networks. A large amount of literature exists on the creation of polynomial-time approximation algorithms for seeking the minimum CDS in wireless ad hoc networks, and we list a few here: [86–92].

Moreover, the discussion has also been extended to a weighted case, in which we assume that the wireless networks contain different types of sensors with varied data transmission cost. The problem is then formulated on unit disk graphs with node weights [93]. We refer the interested readers to Ref. 94 for a recent survey on study of the minimum CDS in wireless networks. Some other domination variants are also employed in the analysis of mobile ad hoc networks. For instance, Swaminathan [48] implements the weakly connected domination (see the section titled “Connected Dominating Set”) that is attractive in practice since the model would further reduce the number of sensors located.

Domination in Power Network Construction and Social Networks

In addition to constructing wireless ad hoc networks, the domination has also been applied to power network construction. Haynes *et al.* [95] describe a *power domination* problem for the usage of monitoring an electric power system and obtaining the information on its voltage and phase angle. The variant is $\mathcal{NP}$ -complete for general graphs, transformed from 3-SAT, but polynomially solvable on trees.

Kelleher [96] and Kelleher and Cozzens [97] apply the domination to social network graphs, in which they study the relationship between individuals of a group in social activities. These studies also provide another angle to tackle the problem of identifying the independent dominating sets. Let a *status* be a set $W \subseteq V$ of vertices, such that for any two vertices $u, v \in W$, $N(u) \cap (V - W) = N(v) \cap (V - W)$, that is, all the vertices in a status dominate the same set of vertices outside the status. We say that two vertices u and v are *structurally equivalent* if either $N(u) = N(v)$ or $N[u] = N[v]$. Moreover, we have

Theorem 35 [96]. *If a dominating set S of a connected graph G of order $n \geq 2$ is a status, then S is an independent dominating set of cardinality two.*

Theorem 36 [97]. *If a dominating set S of a connected graph G is a structurally equivalent set, then S consists of two independent vertices each of which has degree of $n - 1$.*

We refer the interested readers to Refs 96 and 97 for a detailed proof. On the other hand, socialists are interested in finding every status and every maximal structure equivalent set in a social network graph, which can also be solved by using properties of dominating sets in graphs.

Broadcast Domination Problem

Erwin [98] introduced a *broadcast domination* problem, in which integer powers can be assigned to each vertex, and a vertex with positive power “dominates” itself and all vertices that are at a distance of at most the value of its power assignment away. The *Broadcast domination number* $\gamma_b(G)$ is the minimum sum of all power assigned on each vertex in the dominating set that dominates the graph. Blair *et al.* [99] give a polynomial-time algorithm for solving the problem on trees, interval graphs, and series-parallel graphs. They show that for any proper interval graph G , $\gamma_b(G) = \gamma(G)$.

Given an unweighted and undirected graph, Heggernes and Lokshtanov [100] develop the following polynomial algorithm for solving the optimal broadcast domination problem. For all $i \in V$, define $B(i, f_i)$ as a *ball* of vertex i if assigned with integer power f_i , which corresponds to the set of all vertices that are within a distance of f_i from vertex i . A broadcast domination f is *efficient* if $B(i, f_i) \cap B(j, f_j) = \emptyset$ for all $i, j \in V_f, i \neq j$. For an efficient broadcast domination f on G , define a domination graph $G_f = (V_f, E_f)$ where $E_f = \{(i, j) | N(B(i, f_i)) \cap B(j, f_j) \neq \emptyset\}$. They show that if G is an unweighted graph, there always exists an efficient optimal broadcast domination f' on G . This result leads to the proof that an optimal broadcast always exists such that the degree of any vertex in its associated domination graph $G_{f'}$ is no more than 2, and thus, $G_{f'}$ is either a path or a cycle. These results are the foundation for their polynomial algorithm.

Then, Heggernes and Lokshtanov [100] run a *shortest path* algorithm on a directed auxiliary graph G_u which is polynomially constructed from the original graph G , with respect to each vertex u , such that u belongs to a ball corresponding to one of the endpoint in G_u . Furthermore, we extend the discussion to a weighted case, called the *weighted broadcast domination* problem, in which every edge is associated with a distance value, and a positive integer value of f_v covers some vertex $u \in V$ if and only if $f_v \geq d(u, v)$. We again seek a minimum sum of all integer powers located on a subset of vertices that covers the graph. However, the complexity of the weighted broadcast domination problem remains open [101].

SUMMARY AND OPEN QUESTIONS

In this article, we start with the standard dominating set problem, and discuss domination-related problems in graphs. We relate the domination with independence and irredundance, and state the well-known domination inequality chain. Moreover, the bounds and the algorithmic complexity of each domination variant and the domination chain parameters are discussed in detail. Finally, we describe several applications to which the domination is commonly applied.

The complexity issue associated with many domination-related problems still remains open for many different types of graphs. For instance, the complexity of the independent domination, the weighted domination, and the weighted total domination problems remains open in distance-hereditary graphs [43]. The complexity of the weighted broadcast domination problem is also open for general graphs [101].

Acknowledgments

The author is grateful to Dr. J. Cole Smith, and the anonymous referee(s), whose remarkable suggestions led to an improved version of the article. The author is also thankful to Dr. I. Hicks for his great effort in organizing the article.

DRAMA THEORY

JAMES BRYANT

Professor of Operational Research &
Strategy Sciences, Sheffield
Business School at Sheffield
Hallam University, Sheffield, UK

Drama theory is a theory about how people resolve their differences and was developed to inform strategic interaction: that is, interaction in situations where there is interdependence in the choices made by the individuals involved. It is one of a number of frameworks that developed from game theory in response to the paradoxes that follow from adherence to a strict doctrine of instrumental rationality. Its origins lie in Howard's [1] metagame analysis of which it retains two key features. First, it is a positive approach. That is, it is neither purely formal nor normative: assumptions about the "players" are taken to be empirical statements, testable against actual conditions. Second, it is a nonquantitative approach: numerical utilities, for example, are not used. In addition to these features, drama theory directly addresses the paradoxes of rationality revealed by Howard's original work. In doing so, it takes a different route from alternative derivatives of metagame analysis—the Graph Model [2] and the Theory of Moves [3], for example—since they persist in seeking a "solution" to an interaction within a structure where players' preferences and options are fixed. Drama theory recognizes instead that confrontations are practically resolved by appealing to the wider context within which the "small world" of formal game-theoretic models is set.

Drama theory can be applied to real-life situations involving collaboration or conflict: indeed, the former can too readily morph into the latter. It provides support to people in such situations by offering a language that they can use to represent how those involved say they would like a situation resolved and what they would feel they would have to

do if they cannot reach a solution. From this formulation, the pressures that each party faces can systematically be explored, and hence guidance on the management of the interaction can be developed. There is always a range of ways that the pressures can be handled and, while drama theory tells us about the implications of each of these, it does not attempt to tell people which to choose: that is a matter of personal choice and style. In a competitive situation, these insights may help someone gain advantage. However, often, drama theory is used to help several parties reach an agreement.

Drama theoretic analysis has been carried out of confrontations in international relations, in corporate mergers and alliances, in departmental coworking, and in human relations management. Analyses have been used to create focused role-play training exercises, permitting participants to rehearse new roles or relationships. They have also been used to identify the source of tensions in inter- and intraorganizational relationships and to suggest potential ways of reducing them. Like game theory, the framework is completely general in the way that it distils the essence of a situation and it makes no assumptions about the purpose or the locus of analysis.

"PLAY" IN GAMES AND DRAMA

The word "play" relates to both games and drama. In each arena, it refers to the actions of the collection of parties who drive a situation forward.

Therefore, in a game, several "players" have and make choices as to what they should do. These choices may be constrained by the rules or conventions under which their interaction with others is bound to take place, but the responsibility for making them lies firmly with the players themselves. In deciding what to do they will take account of what other players involved in the situation might simultaneously or subsequently determine to do. Game theory models these

decisions, normally assuming that players seek to attain some objective—perhaps to maximize the benefit for themselves—and that in their interaction they make rational choices that will help them to achieve this aim.

By contrast, situations are “played out” in drama by “characters,” who encountering resistance by, or fearing duplicity in, other characters with whom they are in conflict or with whom they are trying to cooperate, send messages to them about the things that they might or might not do. They communicate to warn or convince the other parties, and thereby transform the shared predicament, so that its prospect represents less of a challenge to their own aspirations. Such strategic communications—strategic in the sense that they are informed by a deliberate intention to change characters’ current stances—precede the eventual deliberation that each character must give (possibly informed by game theory) as to what it shall actually do in the situation. Drama theory models this pre-play communication, where the game to be eventually played is itself negotiated. Using Savage’s [4] distinction between decision making in “small worlds” (where you can “look before you leap”) and in “large worlds” (where you “cross that bridge when you come to it”), game theory is the precise, small-world technology that says how a player should act in a game, whereas drama theory illuminates the large world within which this game-theoretic decision making occurs. They are essential complements to each other.

“Play” and “pre-play” and the corresponding relationship between game theory and drama theory can be clearly illustrated by an initial example involving two characters, Alf and Bet. Suppose that Bet is interested in buying a used car that Alf has for sale. They meet and through discussion get an understanding of the outcome that each is seeking. As often happens in such cases, they disagree on the price. If they cannot agree then Bet fails to win the car and Alf has to find another buyer: neither wants this. Alf is in a quandary as to whether to accept Bet’s low offer, while Bet faces the predicament that Alf may refuse to drop the price he demands. Alf’s hints that Bet should accept his asking

price: if she does not then he is sorry but he will not be able to close the deal. Bet advises Alf to take the amount that she has offered for the car: if he does not then she will look elsewhere. Clearly they face an impasse. Moreover, neither wishes to yield.

The game theoretic approach is to look for an equilibrium: an outcome that no player can better through its own actions, given what others are doing (if anyone thought they could gain advantage by choosing differently, then rationally they would do so). However, in the game being played by Alf and Bet, there is no unique equilibrium. It is actually an example of the game called *Chicken* to which there are two equilibria. This can be readily seen. If Alf stubbornly holds out for a high price, then Bet is better off accepting than walking away from the deal; while if Bet refuses to yield then Alf is better off reducing his price than losing a potential buyer. Either of these outcomes (Alf “wins” or Bet “wins”) could be reached from the impasse but there is no way of telling which. Now had one player been prepared to concede to the other (and the other had known this), then the first could take advantage of the situation, indicate refusal to give way, and so win the game. So there is a risk that each may attempt to force stabilization at its own preferred equilibrium, but in so doing could steer the outcome toward the worst prospect, “no deal.”

Drama theory assumes that the characters communicate before they act. This is not a strong assumption since it includes implicit (e.g., by deeds or attitudes) as well as explicit communication. What characters communicate is their *stands*. There are three elements in a character’s stand:

- *Its position.* which is its proposed solution to the situation. This includes statements about what it intends to do and what it would have others do.
- *Its stated intentions.* what it says it will do, given everyone’s positions and stated intentions.
- *Its expressed doubts.* the doubts that it now has about others’ stated intentions, and the doubts that it would have were any declared position to be achieved.

Exchanges between characters are about these elements, since these tell the other characters what a communication is meant to achieve, and how (i.e., understanding others' stands enables a character to interpret the strategic relevance of what they are saying). Of course, any character may be lying or be disbelieved—drama theory makes no assumptions to the contrary—but this is not relevant to the requirements of the model. Nevertheless, characters' stands are what they try to make credible.

MODELING INTERACTION IN DRAMA THEORY

Return to Alf and Bet. Their stands are modeled in drama theory using a frugal notation originally developed for metagame analysis [1]. The *options board* of Table 1 summarizes all the elements required.

At the left side, the two characters are named and their respective *options*—the things which are for them to decide—are listed. The columns in the main body of the table summarize possible future states of affairs. So in the column headed “Alf’s Position” is his proposal that Bet should agree to the high price he is demanding, while he refuses to accept her low offer: Bet’s contrary position is shown in the next column. Note that both of these require specific actions from each character. The column on the left of these includes the stated intentions of both characters (these can all be written in one column as a character’s intentions just relate to the options about which it has discretion): Alf will refuse to accept Bet’s low offer, and Bet will refuse to agree to Alf’s high price.

Alf and Bet’s expressed doubts are shown by question marks in the table. These are justified as follows. If the characters were in the impasse shown by the leftmost column, then either of them or both together do better not to carry out their stated intentions. Since this is common knowledge (i.e., each knows that the other knows it, etc.), the doubts shown are explained. Incidentally, the modeling does not attempt to distinguish degrees of doubt: either an intention is doubted or it is not.

The options board model used in drama theory does not have an exact counterpart in game theory. While its elements represent the components of a game in the normal form, there is no assumption in the drama theoretic model about whether or not characters’ choices are made simultaneously and independently. Such information is not provided by the options board; nor is the possibility of chance moves.

DILEMMA ANALYSIS

The table also introduces a key feature of drama theoretic modeling: the statement of the characters’ *dilemmas*. Indeed, the analysis of confrontations using drama theory has sometimes been termed *dilemma analysis* because of the centrality of this concept. Dilemmas arise from the attempt by characters to act rationally. There are three generic dilemmas, each named for what it makes it hard for a character to do. Each can face a character *with* another character *over* a particular option. They are as follows:

- *Persuasion Dilemma*. A character faces a persuasion dilemma with another character over an option if it has no doubt that the other character will flout its position on that option.
- *Rejection Dilemma*. A character has a rejection dilemma with another character over an option if the other character doubts that the first character will flout the latter’s position on that option.
- *Trust Dilemma*. A character has a trust dilemma with another character over an option if it doubts whether the other character will support its position on that option.

The persuasion and rejection dilemmas come into play when the characters have incompatible positions; the trust dilemma relates to a situation when they are in agreement. Further, the first two dilemmas may occur in one of two so-called *modes* depending upon whether it is a position or an intention that gives rise to them.

Table 1. Option Board: Car-Purchase Example—Confrontation

	Stated Intentions	Alf's Position	Bet's Position	Alf's Dilemma(s)	Bet's Dilemma(s)
Alf					
Accept low offer	NOT accept low offer	Not accept low offer	~		
Bet					
Agree to high price	??? Agree to high	??? Agree to high	??? Agree to high	Trust	

Looking again at Table 1, persuasion dilemmas in position mode have been noted against each character in the two rightmost columns. How are these explained? Alf's Per(p) dilemma arises because (as presently assumed and encapsulated in the options board) he has no doubt that Bet will not agree to a high price. This contradicts his position that she should do so. The dilemma facing Bet can be understood in the same way. The Rejection dilemmas facing each character arise because each doubts that if it came to a confrontation the other would stand firm.

The identification of dilemmas does not in itself show how a situation may be resolved, but it is an essential step in this direction. A fundamental proposition of drama theory is that characters will seek to eliminate the

dilemmas that they face. Dilemmas cause discomfort and tension and raise the emotional temperature of an interaction. As tempers rise, characters try to escape from the conceptual cul-de-sac at which they are stuck and they notice possibilities that might help them achieve their ambitions. Alternatively, the frustrations of the impasse may cause them to act in a counter-rational manner (i.e., against their declared preferences) and, for example, either press harder for their own position or resign themselves to acceding to the other party's solution. In every case, though, the "game" is transformed.

Let us consider Alf's treatment of his persuasion dilemma with Bet over her refusal to agree to the high (to her) price for the car. What can he do? Alternatives available to him are shown schematically in Fig. 1.

**Figure 1.** Dealing with a persuasion dilemma.

Drama theory does not prescribe which of these pathways might be followed: it is a matter of personal choice, perhaps reflecting the personality of the character concerned. Suppose that he maintains his position, then he will try to get Bet to abandon her opposition. This might be done, for example, by making clearer to her the advantages of her doing so; or by stressing the potential disadvantages of not doing so. The former might involve pointing out that the car is ready to drive away, comes with some “extras” that she may not have appreciated, or is a bargain compared with other cars of a similar age and condition. The latter might mean reminding her that there are few cars of this type presently on the market at this price and that she will be losing a bargain to pass it over. Imagine that Bet is persuaded by such blandishments. Then Alf’s dilemma disappears, and indeed Bet also loses her persuasion dilemma if the option board becomes that shown in Table 2.

However, note that a new dilemma has appeared. The (not unreasonable) assumption has been made that, although Bet has agreed to the price Alf is asking, he is not yet sure that she will honor this promise. This is depicted in the table by the question marks appearing against Bet’s option, signifying that this decision is doubted by Alf. The tilde (~) in the first row of her position column incidentally means that her position on Alf’s action is now undeclared: she does not say one way or the other. To eliminate this trust dilemma, Alf and Bet will need further exchanges. One commonplace tactic in the present case might be, for instance, for Alf to request, or for Bet to offer a deposit to show her good faith in the bargain. The precise route followed is clearly open to

the characters to determine for themselves; what is significant is that the drama theory provides a rationale for and explanations of these routes.

THE DYNAMICS OF INTERACTION: EPISODIC DEVELOPMENT

It might be thought that this is the end of the affair between Alf and Bet, but this is not so. Recall that it was stated earlier that drama theory and game theory are complementary, the former being relevant to pre-play communication and the latter to action choices in play. Supposing all dilemmas have been eliminated between characters as just outlined for Alf and Bet, then they have still to take the actions upon which they have agreed: Alf to sell the car for the agreed price and Bet to provide her deposit as a precursor to making the purchase at the amount settled between them. But this is the point at which each must act independently to implement these decisions. And as Bet reflects alone (or possibly with a partner, but in any event away from Alf), she may size up the agreement differently and conclude that the car is not such a bargain after all. If so, then she may renege on the deal, possibly even risking losing her deposit in the process. In the same way, Alf may be approached by a third party who makes a better offer than the one he has concluded with Bet, and he may feel like finding an excuse for withdrawing from the settlement with Bet. He might even use game theory to evaluate this possibility, as shown in Table 3.

If the payoffs were seen as shown, then Alf is clearly better off selling to the third party, regardless of what Bet decides. However, Bet

Table 2. Option Board: Car-Purchase Example—Cooperation

	Stated Intentions	Alf's Position	Bet's Position	Alf's Dilemma(s)	Bet's Dilemma(s)
Alf					
Accept low offer	??? NOT accept low	NOT accept low offer	Accept low offer	Rej (t)	Per (p)
Bet					
Agree to high price	??? NOT agree to	Agree to high price	NOT agree to high	Per (p)	Rej (t)

Table 3. Option Board: Car-Purchase Example—Alf's Game

In each cell (Payoff to Alf, Payoff to Bet)		Bet's Choices	
		Withdraw	Honor Deal
Alf's Choices	Sell to third party	4,3	3,1
	Sell to Bet	1,2	2,4

**Figure 2.** A “Dramatic” episode.

does not have a corresponding choice “no-matter-what.” If Alf does decide to sell to the third party, then Bet’s best decision is to withdraw (and at least not lose face by foolishly honoring the deal).

The overall process of interaction just described can be depicted as in Fig. 2. Earlier episodes shape the context for interaction within which certain issues must be settled by certain characters. These characters explore each other’s views in a tentative manner and thereby create a common reference frame (they are then able to communicate unambiguously). If the communicated intentions are compatible, then there is potential collaboration: otherwise there is confrontation. As has been shown in the car-selling example, confrontation may turn into collaboration; but of course the reverse is also true. Eventually, parties commit to cooperate or to engage in conflict and take actions that may or may not reflect these declared commitments. The actions lead to the denouement: an irreversibly altered environment. The episodic process shown in Fig. 2 is just one fragment of the larger tree comprising antecedent and possible successor episodes.

Before leaving the example involving Alf and Bet, it is important to draw out another key assumption of drama theory. This is that movements to eliminate dilemmas are accompanied by specific emotions. The corollary is that emotion plays an integral role in enabling characters to adjust their positions, intentions, or doubts. Returning briefly to Alf’s persuasion dilemma: if he takes the encouraging road of cajoling Bet into accepting a higher price because of benefits that she had not previously appreciated, then he should do this with positive emotion (in a friendly, generous way) rather than in a bullying, browbeating manner. Drama theory associates specific types of emotion—positive, negative, or neutral—with the dissolution of dilemmas along different pathways. This aspect of the theory was first explored by Bennett and Howard [5] and has been developed in subsequent work.

FORMAL TREATMENT OF DRAMA THEORY

The following statement of the theory is based on Howard [6]: The central concept in drama

theory is that of a frame. A *frame*, F , is a structure having these elements:

- a set C (called the *Cast*) of characters;
- a set A of actions available to the players in C ;
- a function $O: A \rightarrow C$ from the set of actions to the set of characters (i.e., it tells us who “owns” each action);
- for each character $c \in C$:
 - *Position* p_c . this is a subset of A such that $p_c \cap A(k) \neq \emptyset$ for all $k \in C$: that is, c ’s position intersects with every character’s set of available actions. It is the set of actions that c can countenance;
 - *Intentions* n_c . these are a subset of $A(c)$ such that $n_c \cap A(c) \neq \emptyset$: that is, c ’s intentions intersect with each member of its set of available actions. It is the set of its own actions that c says it is considering;
 - *Doubted Actions* d_c . this is a subset of A such that $d_c \cap A(c) \neq n \cap A(c)$ for all $A(c)$: that is, the actions which c doubts must not coincide with its intentions. It is the set of actions about which c is sceptical of the assertions (to accept or implement) made by others.

The triple (p_c, n_c, d_c) is called the *stance* of the character.

These definitions allow us to define three dilemmas by defining three sets of dilemmatic actions:

- Character c ’s *Persuasion Dilemma*, $Per(c, k)$, with character k corresponds to the set of actions $n_k - d_c - p_c$. This is the set of actions that k says it is considering but that c cannot countenance (they are not in its position) and about which c does not doubt k ’s assertion to implement.
- Character c ’s *Rejection Dilemma*, $Rej(c, k)$, with character k corresponds to the set of actions $n_c \cap d_k - p_k$. This is the set of actions that c says it is considering but that k cannot countenance (they are not in its position) and furthermore

about which k doubts c ’s assertion to implement.

- Character c ’s *Trust Dilemma*, $Tru(c, k)$, with character k corresponds to the set of actions $A_k \cap d_c - n_k - p_c$. This is the set of actions that k claims it has excluded but which c believes it is considering and which c cannot countenance (they are not in its position).

Characters are motivated to eliminate their dilemmas because, unless they do so, they must assume that either their stated intentions are disbelieved or their positions will be flouted. If all dilemmas are eliminated, stated intentions implement every position and every player assumes that its position will be implemented.

The fundamental theorem of drama theory is that if and only if all three dilemma sets are empty for all c, k then:

1. Stated intentions implement every position (i.e., $n \subseteq p$, where $p = \cap p_c$).
2. Intentions assumed by each character implement that character’s position (i.e., $(n - d_c) \cup (d_c - n) \subseteq p_c$ for each c).

There is a corollary. That if all dilemmatic sets are empty, then, provided the set A of actions is nonempty, p is nonempty (i.e., all positions are compatible). That is, a necessary and sufficient condition for a complete trusting agreement is the absence of dilemmas.

During the period of pre-play communication, one frame succeeds another as characters facing dilemmas are motivated to find and communicate emotions and rationalizations that enable them to escape these dilemmas. They are able to do so to the extent both that the then current model permits and to the extent that opportunities for reframing are recognized in the real-world situation.

APPLICATIONS

Drama theory can be applied in a number of ways. Clearly, it provides a basis for analyzing interactions. Such analysis might be used to inform or support one or more of

the parties involved: it would be expected that analysis should help parties handle their interactions more effectively. The results of analysis might also be used to capture the essentials of a situation so as to provide a “snapshot” of its strategic state: this could, for example, be useful as a means of briefing an incoming manager and taking over an ongoing business relationship. However, such a summary might alternatively be used to shape a simulation or role play for the purposes of training or development. Personnel could be exposed in an artificial environment to encounters or group situations that are tightly defined (in terms of the dilemmas that they embody) for which they would be able to test and extend their repertoire of responses. These applications will be examined briefly in turn below.

Drama–Theoretic Analysis

Drama–theoretic analysis has been carried out of situations that are both “real” and fictitious. One example of the former is given by Bryant [7], who studied confrontations in the delivery of UK health services; a contrasting example appears in Howard [8], which despite its necessary fictionalization is based upon actual military operations in a postwar zone. Howard [9] also gave a light-hearted but completely rigorous analysis of the endings of two popular films (“Pulp Fiction” and “Reservoir Dogs”) to demonstrate the subtlety of understanding possible with this form of analysis. Levy *et al.* [10,11] have shown how the theory could be used to help manage global hazards and disasters. A large number of what may best be referred to as *fragments of analysis* have been shared on the dedicated, web-based, drama theory forum at <http://www.dilemmasgalore.com>, which shows how nonexperts are using drama theory to investigate and manage live management challenges. Many of these involve the analysis of interactions between individuals rather than organizations, and can be characterized in organizational terms as relating to human resources issues (e.g., bullying at work). Others have been of topical events. The practice of relying upon news media reports as the basis of the latter has been defended on the grounds that the media

report the stories in which the protagonists see themselves as involved: parties may act so as to try to change this story, but the stories themselves are not “cooked up” by anyone as no one is “in charge.” Of course, that does not mean that the news story should not be augmented by intelligence data, but it usually suffices to model the broad strategic confrontations.

Mediation is a special case that merits further examination. When two (or more) parties are in dispute and a mediator becomes involved in helping them bridge their differences, it might be thought that a drama theory model could be created to assist them. While this is true, it cannot be done in a direct manner. This is because such a model would need to incorporate the very differences and doubts that the parties must overcome and so will not share with each other. However, what a mediator can do is to employ a model, based upon explorations with each party, to identify questions that need to be put to each side if matters are to be resolved. For instance, rather than asking a party if what they are proposing (whether it be a threat or a promise) is credible, the mediator asks the other party if it finds the proposal credible: and if it does not, then the burden is on the first party to make its proposal credible. The analysis specifically highlights the presence of incredible or undeterrable threats and promises and so provides the perfect tool for a mediator.

In many situations, it is appropriate to analyze related interactions taking place at a number of different levels: for example, the transactions between front-line staff and customers, between staff within a department, between functional or product departments, and between organizations within a partnership, may all need to be understood and in some sense aligned. The notion of an enterprise confrontation management system (ECMS) has been proposed [12] so that the above can be better accomplished, representing a civil version of the C2CC system developed for the military [13].

Immersive Drama

Completed analyses provide the foundations for the purposeful construction of simulations

and role-plays. Most directly, the role-players take on the parts of the “real” characters in the analyzed situation. Their briefing documents consist of “their” character’s option boards (though possibly presented in a less spartan format) supplemented by other background information of a more conventional form. The former provide them with an immediate prompt for their interactions with other role-players, since they must seek to resolve their dilemmas, and to do this they have to engage in strategic communication with others. A full discussion of the creation and running of such a developmental role-play is given in Bryant and Darwin [14].

SOFTWARE SUPPORT FOR DRAMA ANALYSIS

Drama analysis for whatever purpose can be a time-consuming and demanding activity. Fortunately, some software tools have now appeared (e.g., Confrontation Manager™ software [15]) to ease this burden. These enable users to represent complex situations with the options board notation, so that a hierarchy of confrontations is captured. The software also identifies the dilemmas facing characters, provides an explanation for them, and suggests ways in which these dilemmas might be eliminated. While Confrontation Manager was produced in collaboration with the defense sector, it is quite general in the way that situations are modeled.

DTMCs WITH COSTS AND REWARDS

In many applications, it is of great relevance to associate a reward, often in monetary terms, to a state occupancy or to a state transition of a discrete-time Markov chain (DTMC). A DTMC with an attached reward structure is called the *DTMC with rewards* [1, Vol. 2]. When the amounts of rewards are negative, we have a DTMC with costs. A DTMC with rewards or costs can be used to study problems such as corporate profits and portfolio performance, but as we will illustrate by examples in the subsequent sections, such models can also be broadly applied to many other types of problems.

Denote $\{X_n, n \geq 0\}$ as a *homogeneous* DTMC with the one-step transition probability matrix $P = \{p_{ij}\}$ and the discrete state space S (see Ref. 2 for treatments of nonhomogeneous Markov and semiMarkov reward processes). Suppose that each occupancy of state i is associated with some random reward R_i with the expected reward $E[R_i] = r_i, i \in S$. The system will receive a sequence of rewards as the Markov chain evolves over time. We assume that rewards are uniformly bounded; that is $|r_i| \leq B < \infty$, for all $i \in S$.

We shall consider several commonly used performance measures in Markov reward models in the subsequent subsections.

Expected Total Reward

In this section, we consider two performance measures in turn. The first performance measure is the expected total reward over a

finite number of transitions, and the second performance measure is the expected total reward the system receives until the process enters a designated (e.g., an absorbing) state.

We denote the expected total reward of a DTMC over a fixed-time interval n , given the process starts in state $X_0 = i$, by $g_i(n)$, which can be expressed as

$$g_i(n) = E \left[\sum_{k=0}^n R_{X_k} | X_0 = i \right]. \quad (1)$$

Denote column vectors $r = \{r_i, i \in S\}$ and $g(n) = \{g_i(n), i \in S\}$, respectively, as the expected occupancy reward vector and the expected total reward (over $n + 1$ periods) vector. Denote also $M(n) = \{m_{ij}(n), i, j \in S\}$, where $m_{ij}(n)$ represents the expected number of times the Markov chain, starting in state $X_0 = i$, visits state j during the first $n + 1$ transitions. It is known that $M(n)$ satisfies the following equation [3]:

$$M(n) = \sum_{k=0}^n P^k. \quad (2)$$

Then, it is intuitively appealing and can indeed be shown formally (Theorem 5.11 of Ref. 4), that

$$g_i(n) = \sum_{j \in S} m_{ij}(n) r_j. \quad (3)$$

In matrix form, the previous expression is written as $g(n) = M(n)r$.

Example 1. A periodic-review inventory system with an (s,S) policy. We consider a periodic-review inventory system with lost sales and instantaneous order replenishment. Suppose weekly demands for an item are independently and identically distributed (iid) random variables with the common distribution

$$P(D = d) = p_d, \quad d = 0, 1, 2, \dots \text{ and } \sum_{d=0}^{\infty} p_d = 1.$$

Suppose the system uses a replenishment policy of the (s, S) type: if at the beginning of week n the stock on hand, X_n , is lower than s , then we place an order to bring the inventory level to S ; otherwise, we do not order. Assume also that the system incurs a holding cost of h per unit at the end of a week, a shortage cost of p per unit of unmet demand, a fixed ordering cost of K for placing an order, and a variable cost of c per unit ordered.

The stochastic process $\{X_n, n \geq 0\}$ forms a Markov chain with the state space $\{0, 1, \dots, S\}$, where

$$X_{n+1} = \begin{cases} \max\{X_n - D_n, 0\}, & \text{if } X_n \geq s, \\ \max\{S - D_n, 0\}, & \text{if } X_n < s, \end{cases}$$

where D_n is the demand in week n . We need to distinguish two cases, $i \geq s$ and $i < s$. In the former case, we obtain the transition probabilities of the Markov chain as

$$p_{ij} = \begin{cases} p_{i-j}, & 1 \leq j \leq i, \\ \sum_{d=i}^{\infty} p_d, & j = 0, \end{cases}$$

and for $i < s$,

$$p_{ij} = \begin{cases} p_{s-j}, & 1 \leq j \leq S, \\ \sum_{d=i}^{\infty} p_d, & j = 0. \end{cases}$$

Let us compute the expected total cost the system incurs over the next 12 weeks, assuming the system holds no stock at time 0; that is, $X_0 = 0$. To proceed, we need to compute $m_{0j}(11)$, the expected number of weeks the system has j units of ending inventory during the next 12 weeks, given that it initially has 0 units on hand, for $j \in S$. This quantity can be obtained from Equation (2), $M(11) = \sum_{k=0}^{11} P^k$. The expected weekly cost when the system starts with i units of stock on hand is given by

$$r_i = \begin{cases} K + c(S - i) + hi + p \sum_{d=S}^{\infty} (d - S)p_d, & i < s, \\ hi + p \sum_{d=i}^{\infty} (d - i)p_d, & i \geq s. \end{cases}$$

From Equation (3), the expected total cost of the inventory system over the next 12 weeks becomes

$$\begin{aligned} g_0(11) &= \sum_{j=0}^S m_{0j}(11) r_j \\ &= \sum_{j=0}^{s-1} m_{0j} \left(K + c(S - j) + hj \right. \\ &\quad \left. + p \sum_{d=S}^{\infty} (d - S)p_d \right) \\ &\quad + \sum_{j=s}^S m_{0j} \left(hj + p \sum_{d=j}^{\infty} (d - j)p_d \right). \end{aligned}$$

Next, we consider the expected total reward the system receives until it enters a final state. In this case, since the time until the process reaches the final state is random, the duration that the process accumulates rewards is also random. Without loss of generality, we designate the final state as 0. Since the problem does not depend on what happens after the final state is reached, we can treat state 0 as an absorbing state. That is, we modify the transition probabilities by setting $p_{00} = 1, p_{0j} = 0$, for $j > 0$, and leaving p_{ij} unchanged for all $i > 0$ and all j .

Let g_{i0} be the expected total reward received by the system, starting in state i until the first entrance of the final state 0, with $v_{00} = 0$. Since g_{i0} is simply the present reward r_i plus the expected total reward from whatever state is entered in the next period, we can obtain g_{i0} by solving simultaneous equations:

$$g_{i0} = r_i + \sum_{j \in S} p_{ij} g_{j0}, \quad i \in S. \quad (4)$$

These simultaneous equations, with $g_{00} = 0$, has a unique solution (Lemma 2, p. 124 of Ref. 5). This method is known as the *first-step analysis*, because we condition on the first step, viz $X_1 = j$, that the system visits.

We demonstrate the use of Equation (4) in the following example.

Example 2. Expected first passage time. One problem of interest in the study of stochastic processes is to compute the expected first passage time from states i to j , which is the expected number of transitions the process takes for its first entrance from state i to state j . In this example, we consider a discrete-time queue that can accommodate at most N customers. Suppose we wish to find the expected total time all customers spent in the system, starting at an integer time when i customers are present and ending at the time when the system first becomes empty. From Little's Law, this total waiting time is the sum of the numbers of customers in the system, summed over the first passage time from state i to state 0. We let $r_i = i$ be the "reward" in state i , and let g_{i0} be the expected total waiting time of all customers until the system becomes empty, starting at a time when there are i customers in the system, with $g_{00} = 0$. Once the transition probability matrix P of this discrete-time queue is specified, we can use Equation (4) to obtain the unique solution of the simultaneous linear equations:

$$g_{i0} = i + \sum_{j=0}^N p_{ij} g_{j0}, \quad i = 1, \dots, N.$$

If the total rewards received in a Markov reward model are infinite as the number of transitions tends to infinity, it becomes appropriate to consider a performance measure such as the *discounted reward* or the *long-run average reward*. We shall consider these two measures in the following two sections.

Discounted Reward

In discounted reward models, rewards received in future periods are discounted by a discount factor $0 < \beta < 1$. Define g_i^β as the expected total β -discounted reward received over an infinite horizon, given $X_0 = i$. Then,

$$g_i^\beta = r_i + E \left[\sum_{k=1}^{\infty} \beta^k (R_{X_k} | X_0 = i) \right].$$

Conditioning on the next state the process enters in period 1 (the first-step analysis), we obtain

$$\begin{aligned} g_i^\beta &= r_i + E \left[\sum_{k=1}^{\infty} \beta^k (R_{X_k} | X_0 = i) \right] \\ &= r_i + \beta \sum_{j \in S} \left(r_j + E \left[\sum_{k=2}^{\infty} \beta^{k-1} (R_{X_k} | X_1 = j) \right] \right) \\ &\quad \times p_{ij} \\ &= r_i + \beta \sum_{j \in S} \left(r_j + E \left[\sum_{k=1}^{\infty} \beta^k (R_{X_k} | X_0 = j) \right] \right) \\ &\quad \times p_{ij} \\ &= r_i + \beta \sum_{j \in S} g_j^\beta p_{ij}. \end{aligned}$$

Note that we have not made any assumptions on transition probability matrix P . This means that the above expression holds for any Markov chain; that is, we do not require the Markov chain to be irreducible and positive recurrent.

Let $g^\beta = \{g_i^\beta, i \in S\}$ be the column vector corresponding to the discounted rewards g_i^β . In matrix form, the previous expression is given by

$$g^\beta = r + \beta P g^\beta, \quad (5)$$

or, equivalently,

$$g^\beta = (I - \beta P)^{-1} r, \quad (6)$$

where I is the identity matrix and matrix $(I - \beta P)$ is invertible if $0 < \beta < 1$.

Example 3. A Vehicle Insurance Problem. A transport firm has an insurance contract for a fleet of vehicles it owns. The premium payment is due at the beginning of each year. There are three possible premium classes with a premium payment of P_j for class j , with $P_3 < P_2 < P_1$. The premium class of the firm in a given year depends on its premium class and claim history during the past year. In case no damage is claimed in the past year and the previous premium is P_j , the next premium is P_{j+1} (with $P_4 = P_3$, by convention); otherwise, the highest premium P_1 is due. Since the insurance contract is for a whole fleet of vehicles, the transport firm has obtained the option to decide only

at the end of the year, whether the accumulated damage during that year should be claimed or not. Under a given claim limit policy $(\alpha_1, \alpha_2, \alpha_3)$, the transport firm claims only damages larger than α_j when the current premium class is j . In case a claim is made, the insurance company compensates the accumulated damage minus an own risk, which amounts to d_j for premium class j . The total damages in successive years are iid random variables with a common cumulative distribution function F and a density function f . The transport firm is interested in determining the expected discounted total payment of premiums under the claim limit policy $(\alpha_1, \alpha_2, \alpha_3)$.

Define X_n as the premium class for the transport firm at the beginning of year n . The stochastic process $\{X_n, n \geq 0\}$ is a DTMC with three possible states $j = 1, 2, 3$. The one-step transition probability matrix of this Markov chain works out as

$$P = \begin{bmatrix} 1 - F(\alpha_1) & F(\alpha_1) & 0 \\ 1 - F(\alpha_2) & 0 & F(\alpha_2) \\ 1 - F(\alpha_3) & 0 & F(\alpha_3) \end{bmatrix}. \quad (7)$$

The expected cost per year associated with premium class j is given by

$$r_j = P_j + \int_0^{\alpha_j} x f(x) dx + \beta d_j (1 - F(\alpha_j)). \quad (8)$$

In the previous expression, we see that the expected annual costs of the firm in premium class j include the annual premium of class j , the expected damage absorbed by the firm by not filing the claims when the accumulated damage is less than α_j , and the deductible when the accumulated damage exceeds the claim limit α_j . The expected deductible given in the last term of the above expression is discounted by β to reflect the timing of the payment. From Equation (5), we can compute the discounted payment of the firm by solving the following simultaneous equations:

$$\begin{aligned} g_1^\beta &= r_1 + \beta \left[(1 - F(\alpha_1)) g_1^\beta + F(\alpha_1) g_2^\beta \right] \\ g_2^\beta &= r_2 + \beta \left[(1 - F(\alpha_2)) g_1^\beta + F(\alpha_2) g_3^\beta \right] \\ g_3^\beta &= r_3 + \beta \left[(1 - F(\alpha_3)) g_1^\beta + F(\alpha_3) g_3^\beta \right]. \end{aligned}$$

Average Reward

The average reward per unit time is a commonly used criterion to measure the reward rate associated with a Markov reward model, which is defined as

$$g_i = \lim_{n \rightarrow \infty} \frac{1}{n+1} E \left[\sum_{k=0}^n R_{X_k} | X_0 = i \right].$$

For expositional simplicity, we only consider irreducible and positive recurrent Markov chains. Again, we assume that rewards are uniformly bounded, $|r_i| \leq B < \infty$. Let the column vector $\pi = \{\pi_i, i \in S\}$ be the stationary distribution of the DTMC, satisfying $\pi = \pi P$ and $\sum_{i \in S} \pi_i = 1$. To compute g_i , we note

$$\begin{aligned} g_i &= \lim_{n \rightarrow \infty} \frac{1}{n+1} E \left[\sum_{k=0}^n R_{X_k} | X_0 = i \right] \\ &= \lim_{n \rightarrow \infty} \frac{1}{n+1} \left[\sum_{k=0}^n \sum_{j \in S} r_j p_{ij}^{(n)} \right] \\ &= \sum_{j \in S} \left[\lim_{n \rightarrow \infty} \frac{1}{n+1} \sum_{k=0}^n p_{ij}^{(n)} \right] r_j \\ &= \sum_{j \in S} \pi_j r_j, \end{aligned}$$

where $p_{ij}^{(n)} = P(X_{n-1} = j | X_0 = i)$. The interchange of limits and summations in the third step is justified because $\sum_{i \in S} \pi_i = 1$ and rewards are uniformly bounded. Notice that the average reward g_i is independent of initial state i . Therefore, the average reward per unit time satisfies

$$g = \sum_{j \in S} \pi_j r_j. \quad (9)$$

We illustrate the use of Equation (9) with two examples.

Example 3. (continued). Consider the DTMC model of the vehicle insurance problem as described in Example 3. Suppose the firm now wishes to determine its long-run average annual payment under the claim limit policy $(\alpha_1, \alpha_2, \alpha_3)$. Since the DTMC is irreducible and positive recurrent, we can

compute its stationary distribution by $\pi = \pi P$ and $\sum_{i=1}^3 \pi_i = 1$. The steady-state probabilities are

$$\begin{aligned}\pi_1 &= \frac{1 - G(\alpha_3)}{1 - G(\alpha_3) + G(\alpha_1) - G(\alpha_1)G(\alpha_3) + G(\alpha_1)G(\alpha_2)} \\ \pi_2 &= \frac{(1 - G(\alpha_3))G(\alpha_1)}{1 - G(\alpha_3) + G(\alpha_1) - G(\alpha_1)G(\alpha_3) + G(\alpha_1)G(\alpha_2)} \\ \pi_3 &= \frac{G(\alpha_1)G(\alpha_2)}{1 - G(\alpha_3) + G(\alpha_1) - G(\alpha_1)G(\alpha_3) + G(\alpha_1)G(\alpha_2)}.\end{aligned}$$

Finally, with the cost expression given in Equation (8), we can use Equation (9) to determine the long-run average annual payment of the transport firm.

In many applications, it is also common to associate rewards with state transitions instead of state occupancies. In this case, let r_{ij} denote the expected reward associated with a transition from state i to state j . Then, the expected reward associated with a transition from state i is $r_i = \sum_j p_{ij} r_{ij}$. We illustrate this concept with the following example.

Example 4. Taxicab Fare. Suppose a metropolitan area is partitioned into three zones, with states 1, 2, and 3 representing zones 1, 2, and 3, respectively. Denote $\{X_n, n \geq 0\}$ as a Markov chain, where X_n is the location of a taxicab after n trips. The probability that a customer boarding in state i needs a ride to state j is p_{ij} , and the fare for such a trip is r_{ij} . For this example, the transition matrix and transition reward matrix are given by

$$P = \{p_{ij}\} = \begin{bmatrix} 1/2 & 1/4 & 1/4 \\ 1/2 & 1/4 & 0 \\ 3/4 & 1/4 & 0 \end{bmatrix} \quad \text{and} \quad \{r_{ij}\} = \begin{bmatrix} 10 & 20 & 40 \\ 20 & 20 & 40 \\ 40 & 40 & - \end{bmatrix},$$

respectively. We are interested in computing the average fare per trip. To proceed, we first note that the expected fare associated with a ride starting from state i is $r_i = \sum_j p_{ij} r_{ij}$. From the above matrices, we obtain $r = (r_1, r_2, r_3) = (20, 25, 40)$. The stationary distribution of the Markov chain can be solved by $\pi = \pi P$ and $\sum_{i=1}^3 \pi_i = 1$, which yields the solution $(\pi_1, \pi_2, \pi_3) = (11/20, 5/20, 4/20)$. Therefore, the average fare per trip is given by

$$g = \sum_{j=1}^3 \pi_j r_j = 1010/40 = \$25.25.$$

For further readings of discrete-time Markov reward models and their applications, the reader is referred to Refs 2, 4–8, among others.

DUAL SIMPLEX

MIHAI BANCUIU
School of Management,
Bucknell University,
Lewisburg, Pennsylvania

Consider the following linear programming (LP) problem P expressed in standard form:

$$\begin{aligned} \text{[P]} \quad & \min \mathbf{c}^T \mathbf{x} \\ & \text{subject to: } \mathbf{Ax} = \mathbf{b} \\ & \mathbf{x} \geq 0, \end{aligned}$$

where $\mathbf{c}^T = (c_1, c_2, \dots, c_n) \in \mathbf{R}^n$ is an n -dimensional cost vector, $\mathbf{A} = (a_{ij}) \in \mathbf{R}^{m \times n}$ is a matrix of constraint coefficients, $\mathbf{b} = (b_1, b_2, \dots, b_m)^T \in \mathbf{R}^m$ is an m -dimensional right hand side (RHS) vector, and $\mathbf{x} = (x_1, x_2, \dots, x_n)^T \in \mathbf{R}^n$ is an n -dimensional vector of decision variables. We refer to the total cost $z = \mathbf{c}^T \mathbf{x} : \mathbf{R}^n \mapsto \mathbf{R}$ as the objective value of problem P . Stated in this form, P is called the *primal* problem, and the vector $\mathbf{x}^*$ that minimizes the objective function $\mathbf{c}^T \mathbf{x}^*$, while satisfying the equality condition $\mathbf{Ax}^* = \mathbf{b}$, is called the *optimal solution* to the problem P . Associated with the primal problem P , there exists a dual problem D , which is formulated in the following way:

$$\begin{aligned} \text{[D]} \quad & \max \mathbf{b}^T \mathbf{u} \\ & \text{subject to: } \mathbf{A}^T \mathbf{u} \leq \mathbf{c} \\ & \mathbf{u} \text{ free.} \end{aligned}$$

Here, the vector $\mathbf{u} = (u_1, u_2, \dots, u_m) \in \mathbf{R}^m$ is called the vector of *dual variables*. Notice that formulating the dual problem of D will yield the original primal problem P . The relationship between problems P and D is established by the following two theorems (the proofs of these and any subsequent result presented in this article can be found in any introductory LP textbook (see Refs 1, 2; **LP Duality and KKT Conditions for LP**).

Theorem 1 [Weak Duality]. *If $\mathbf{x}$ is a feasible solution of P , and $\mathbf{u}$ is a feasible solution of D , then $\mathbf{b}^T \mathbf{u} \leq \mathbf{c}^T \mathbf{x}$.*

Theorem 2 [Strong Duality]. *If problem P has an optimal solution, then problem D also has an optimal solution. Moreover, the respective optimal solution values are equal to one another.*

An immediate consequence of weak duality is that if the primal problem P is unbounded from below, then its dual D must be infeasible, and correspondingly, if the dual problem D is unbounded from above, then the primal P must be infeasible. Additionally, if the choice of $\mathbf{x}$ and $\mathbf{u}$ is such that the inequality described in the weak duality theorem becomes an equality, then $\mathbf{x}$ and $\mathbf{u}$ are the optimal solutions to P and D , respectively. The optimality of $\mathbf{x}$ and $\mathbf{u}$ can also be verified by the *complementary slackness* conditions.

Theorem 3 [Complementary Slackness]. *Let $\mathbf{x}$ and $\mathbf{u}$ be feasible solutions to P and D , respectively. Then, $\mathbf{x}$ and $\mathbf{u}$ are optimal solutions for each problem if and only if $\mathbf{u}^T(\mathbf{Ax} - \mathbf{b}) = 0$ and $(\mathbf{c} - \mathbf{A}^T \mathbf{u})^T \mathbf{x} = 0$.*

Theorem 3 implies three things. First, observe that in problem P , the first complementary slackness condition, that is $\mathbf{u}^T(\mathbf{Ax} - \mathbf{b}) = 0$, is automatically satisfied (since P is expressed in standard form). Second, the complementary slackness theorem states that in problem D , if any constraint is not tight, then the corresponding value of the primal variable corresponding to each such constraint is 0. If the constraint is tight, then the corresponding primal value is nonnegative. Finally, the theorem provides an easy way of translating primal solutions into corresponding dual solutions, and vice versa, as well as providing a certificate for whether a proposed solution for P is, in fact, optimal. The following example illustrates this last property.

Example [Complementary Slackness]. Consider the following LP expressed in standard form, together with its dual:

$$\begin{aligned}
 &\min && 3x_1 + 4x_2 - x_3 \\
 &\text{subject to:} && 3x_1 - 4x_2 + 2x_3 = 8 \\
 &&& 4x_1 - 2x_2 + 5x_3 = 22 \\
 &&& x_1, x_2, x_3 \geq 0. \\
 &\max && 8u_1 + 22u_2 \\
 &\text{subject to:} && 3u_1 + 4u_2 \leq 3 \\
 &&& -4u_1 - 2u_2 \leq 4 \\
 &&& 2u_1 + 5u_2 \leq -1.
 \end{aligned}$$

Suppose we are presented with the solution $\mathbf{x} = (0, 0.25, 4.5)$ and wish to establish optimality via complementary slackness. The first complementary slackness condition is automatically satisfied, because the problem is in standard form. Since $x_2 > 0$ and $x_3 > 0$, from the second complementary slackness condition we obtain $-4u_1 - 2u_2 = 4$ and $2u_1 + 5u_2 = -1$, which on solving, gives $\mathbf{u} = (-1.125, 0.25)$. This solution is dual feasible, as it also satisfies the first constraint of the dual problem, and the total cost is -3.5 . This is the same cost of the primal problem; therefore, by the strong duality theorem, $\mathbf{x}$ is an optimal solution to the original LP.

The following theorem establishes the Karush–Kuhn–Tucker (KKT) conditions for an LP problem. For more advanced discussions on the topic, consult the article titled **LP Duality and KKT Conditions for LP** in this encyclopedia.

Theorem 4 [KKT Optimality Conditions for LP]. *Given an LP problem P , the vector $\mathbf{x}$ is an optimal solution to P if and only if there exist vectors $\mathbf{u}$ and $\mathbf{r}$ such that*

1. $\mathbf{Ax} = \mathbf{b}, \mathbf{x} \geq 0$ (primal feasibility),
2. $\mathbf{A}^T \mathbf{u} + \mathbf{r} = \mathbf{c}, \mathbf{r} \geq 0$ (dual feasibility),
3. $\mathbf{r}^T \mathbf{x} = 0$ (complementary slackness).

In Theorem 4, the vector $\mathbf{r}$ is simply the vector of slack/surpluses $\mathbf{c} - \mathbf{A}^T \mathbf{u}$ from the dual problem D . In the primal problem P , the

vector $\mathbf{r}$ is referred to as the vector of reduced costs, and it is usually denoted by $\bar{\mathbf{c}}$.

From a computational perspective, the importance of the theorem is that a computer algorithm designed to solve problem P using an extreme vertex approach on the polyhedron described by the constraints of P , can work in one of two possible ways. The first approach is to make sure that both primal feasibility and complementary slackness are preserved at every iteration of the algorithm, while seeking dual feasibility only at the optimal solution. The second approach is to ensure dual feasibility and complementary slackness during every iteration, while seeking primal feasibility only at the optimal solution. The first approach yielded George Dantzig’s (primal) *simplex algorithm* around 1947 [3–5], which is, arguably, the cornerstone of the entire linear optimization literature. The second method led to the discovery of the *dual simplex algorithm*, in 1954 by Carlton Lemke [6].

While the simplex algorithm, in its both incarnations, has shown remarkably good performance in practice, in that it usually requires $O(m)$ iterations (pivots), there exist instances where an exponential number of iterations may be required until an optimal solution is found (see Ref. 7 for the first description of instances that lead to a performance on the order of $O(2^n)$). Hence, later theoretical efforts are concentrated on a different attack for solving the LP problem. These efforts were successful, first in 1979 when Leonid Khachian [8] discovered the ellipsoidal method for solving the LP problems in polynomial time, and later in 1984 with Narendra Karmarkar’s discovery of the first interior point method [9], which created a very fertile research area in subsequent years (see the section titled “Non-simplex Algorithms for LP” in this encyclopedia for more information). In the following section, we will discuss the theory and the implementation of the dual simplex algorithm.

DUAL SIMPLEX ALGORITHM

Throughout this section, we assume familiarity with basic linear algebra concepts, such

as bases, spaces, and polyhedra, as well as an understanding of the (revised) simplex algorithm, which is described in the article titled *The Simplex Method and Its Complexity* in this encyclopedia.

Assume that the coefficient matrix $\mathbf{A}$ is of full rank $m(m < n)$, and that there exist a basis $\mathbf{B}$ corresponding to the m linearly independent columns of $\mathbf{A}$, and a matrix $\mathbf{N}$ that contains the remaining $n - m$ nonbasic columns of $\mathbf{A}$. We partition the solution vector $\mathbf{x}$ into two components $\mathbf{x}_B = \mathbf{B}^{-1}\mathbf{b} = (x_1, x_2, \dots, x_m)^T$ and $\mathbf{x}_N = (x_{m+1}, x_{m+2}, \dots, x_n)^T = \mathbf{0}$, called the *basic* and *nonbasic* solutions, respectively. In a similar fashion, we partition the cost vector $\mathbf{c}^T = [\mathbf{c}_B | \mathbf{c}_N]$ into a basic and a nonbasic component, that is, $\mathbf{c}_B$ and $\mathbf{c}_N$, which are the cost coefficients associated with $\mathbf{x}_B$ and $\mathbf{x}_N$, respectively. Suppose, moreover, that the basis $\mathbf{B}$ induces a dual feasible solution $\mathbf{u}$, that is, $\mathbf{A}^T \mathbf{u} \leq \mathbf{c}$ and $\mathbf{u}^T = \mathbf{c}_B^T \mathbf{B}^{-1}$. It is easy to see that the equality constraints of P are satisfied, since

$$\mathbf{A}\mathbf{x} = [\mathbf{B} | \mathbf{N}] \begin{bmatrix} \mathbf{B}^{-1}\mathbf{b} \\ \mathbf{0} \end{bmatrix} = \mathbf{b}$$

and that complementary slackness is also satisfied, since

$$\begin{aligned} (\mathbf{c} - \mathbf{A}^T \mathbf{u})^T \mathbf{x} &= \mathbf{c}^T \mathbf{x} - \mathbf{u}^T \mathbf{A}\mathbf{x} \\ &= \mathbf{c}^T \mathbf{B}^{-1}\mathbf{b} - \mathbf{c}_B^T \mathbf{B}^{-1}\mathbf{b} = 0 \end{aligned}$$

The only missing ingredient for an optimal solution to P is the requirement that $\mathbf{x}_B = \mathbf{B}^{-1}\mathbf{b} \geq \mathbf{0}$. If this inequality happens to hold, then $\mathbf{x}$ is optimal for P , since all conditions of Theorem 4 are met. On the other hand, if there exists at least one negative entry in $\mathbf{x}_B$, then we perform a change of basis that eliminates this entry from $\mathbf{B}$, thus reducing the primal infeasibility. The procedure repeats until all entries in $\mathbf{x}_B$ are nonnegative. This is the essence of the dual simplex algorithm.

Naturally, the two questions that arise are about how this change of basis is actually performed, and whether or not the new solution obtained after the basis change is actually an improvement over the old one. The following subsections describe the actual

flow of the dual simplex algorithm, alongside with a discussion on several theoretical and practical implementation challenges.

Summary of the Dual Simplex Method: Description and Geometry

The dual simplex method entails the following steps.

Step 0 (Initialization). Find a dual feasible basis $\mathbf{B}$ such that the associated reduced cost vector $\bar{\mathbf{c}} = \mathbf{c} - \mathbf{u}^T \mathbf{A}$ is nonnegative (in the sense that each vector entry is nonnegative). (We will later provide a quick procedure for identifying such a basis.)

Step 1 (Pricing). If $\mathbf{x}_B = \mathbf{B}^{-1}\mathbf{b} \geq \mathbf{0}$, stop; the current solution is optimal. Otherwise, select a pivot row i with the corresponding value of the basic variable $x_i < 0$. If there are multiple candidates, select the one with the minimum value. The variable x_i will leave the basis.

Step 2 (Ratio Test). If all constraint coefficients a_{ij} alongside the i th row are nonnegative ($a_{ij} \geq 0, \forall j$), stop. The dual problem is unbounded, and therefore the primal problem is infeasible. Otherwise, select the pivot column j , by performing the following minimum ratio test:

$$j = \arg \min_{k=1, \dots, m} \left\{ \frac{\bar{c}_k}{a_{ik}} \mid a_{ik} < 0 \right\} \quad (1)$$

The corresponding variable x_j will enter the basis.

Step 3 (Basis Change). Pivot on element a_{ij} and go to step 1.

We will illustrate the dual simplex method by contrasting it with the primal simplex, on a simple example, presented below. We

Table 1. The General Form of a Simplex Tableau

	z	$\mathbf{x}_B$	$\mathbf{x}_N$	RHS
z	1	$\mathbf{0}$	$\mathbf{c}_B^T \mathbf{B}^{-1} \mathbf{N} - \mathbf{c}_N^T$	$\mathbf{c}_B^T \mathbf{B}^{-1} \mathbf{b}$
$\mathbf{x}_B$	$\mathbf{0}$	$\mathbf{I}$	$\mathbf{B}^{-1} \mathbf{N}$	$\mathbf{B}^{-1} \mathbf{b}$

x_1	0	1	0	0	-1	0	1	2

*Pivoting element.

will use the traditional simplex tableau exposition (Table 1), presented in the following fashion (see Ref. 10 for one of the first descriptions of the simplex tableau, and Ref. 11 for a detailed description of this particular implementation form).

Note that in other treatments of LP [1], the reduced costs are defined the other way around, that is, $\mathbf{c}_B \mathbf{B}^{-1} \mathbf{N} - \mathbf{c}_N$. Under this interpretation, the arguments presented below still hold, but the signs are reversed—for example, the algorithm would terminate when all reduced costs are nonnegative (in a minimization example), rather than nonpositive, as we assume.

Example [Primal Simplex]. Consider the following LP problem, together with its corresponding dual:

$$\begin{aligned}
 \min \quad & 2x_1 + x_2 \\
 \text{subject to: } & x_1 + x_2 \geq 3 \\
 & x_1 \geq 2 \\
 & x_1, x_2 \geq 0 \\
 \max \quad & 3u_1 + 2u_2 \\
 \text{subject to: } & u_1 + u_2 \leq 2 \\
 & u_1 \leq 1 \\
 & u_1, u_2 \geq 0.
 \end{aligned}$$

The following primal simplex tableaus (Tables 2a and 2b) solve the primal and the dual problems. For the primal problem, we

Table 2b. Primal Simplex on Dual Problem

	z	u_1	u_2	u_3	u_4	RHS
z	1	3	2	0	0	0
u_3	0	1	1	1	0	2
u_4	0	1*	0	0	1	1
z	1	0	2	0	-3	-3
u_3	0	0	1*	1	-1	1
u_1	0	1	0	0	1	1

u_2	0	0	1	1	-1	1
u_1	0	1	0	0	1	1

*Pivoting element.

use the big- M method to form an initial basis, rather than the two-phase method, to keep everything in one tableau.

The optimal solution to the primal problem is $\mathbf{x} = (2, 1, 0, 0, 0, 0)^T$; the corresponding optimal dual vector is $\mathbf{u} = (1, 1, 0, 0)^T$. The optimal value of the objective function is $z = 5$. One can also quickly check the complementary slackness conditions and verify that they are met.

We will now examine the way in which the dual simplex algorithm operates. First, we look at the dual tableau (Table 3a), with the starting basis given by the surplus variables x_3 and x_4 (and thus, we multiply both rows by -1 to obtain the basis given by the identity matrix $\mathbf{I}_2$). Notice that this basis is primal infeasible, because of the negative terms in $\mathbf{B}^{-1} \mathbf{b}$.

Table 3a. Initial Basis for Dual Simplex

	z	x_1	x_2	x_3	x_4	RHS
z	1	-2	-1	0	0	0
x_3	0	-1	-1*	1	0	-3
x_4	0	-1	0	0	1	-2

*Pivoting element.

Table 3b. First Pivot Using Dual Simplex

	z	x_1	x_2	x_3	x_4	RHS
z	1	-1	0	-1	0	3
x_2	0	1	1	-1	0	3
x_4	0	-1*	0	0	1	-2

*Pivoting element.

Table 3c. Second Pivot Using Dual Simplex

	z	x_1	x_2	x_3	x_4	RHS
z	1	0	0	-1	-1	5
x_2	0	0	1	-1	1	1
x_1	0	1	0	0	-1	2

We are at step 1 of the dual simplex method. We select x_3 as the leaving variable ($-3 < -2$). According to step 2, the problem is not infeasible (two negative entries on the selected row). The entering variable is x_2 , by the minimum ratio test: $\min\{-2/-1, -1/-1\} = 1$. The new tableau is obtained by subtracting row 1 from row 0, and by dividing row 1 by -1 (Table 3b).

The solution is still primal infeasible. The variable x_4 leaves the basis, and x_1 enters, by the minimum ratio test. Row 2 gets subtracted from row 0, row 2 is added to row 1, and row 2 is divided by -1 to get the new tableau (Table 3c).

Since all terms in $\mathbf{B}^{-1}\mathbf{b}$ are positive and all entries in row 0 are negative, this is the optimal basis. The algorithm terminates, with the same solution as reported by the primal simplex above. Since the dual problem maximizes the objective function, the increase in z from one pivot to the next is natural.

Several observations are in order. First, notice the correspondence between the dual simplex, as exhibited in Tables 3a–3c, and the primal simplex method applied to the

dual problem, as shown in Table 2b. Through simple transposition manipulations, we can see that the two tableaus are equivalent. This is important: from a mathematical point of view, the dual simplex method used to solve a primal problem is equivalent to the primal simplex method applied to the dual problem, as long as the dual is not converted into standard form. (Converting the dual problem into standard form could lead to different tableaus.) Second, from a geometrical perspective, the dual simplex iterates around infeasible primal solutions (but dual feasible!), until a solution that is both primal and dual feasible is found. In our example, Table 3a is equivalent to the primal basic infeasible solution $\mathbf{x} = (0, 0, -3, -2)^T$. By complementary slackness, the associated dual solution is $\mathbf{u} = (0, 0)^T$, which is basic feasible in the dual problem. Figure 1, adapted from a similar example presented in Ref. 1, displays the progression of the dual simplex method, in terms of primal and dual basic feasible solutions.

In Fig. 1, the path A–B–C traces, in both spaces, the pivot sequence of the dual simplex applied to the example problem. In the primal space, bases A and B are infeasible, but at optimality, C is feasible. In the dual space, the algorithm maintains feasibility at each base A, B, and finally C. Naturally, the solution is improved during every iteration.

Implementation Issues

Cycling. While iterating, it is possible that the dual simplex can arrive at a situation where the reduced cost associated with the selected pivot column is zero, a situation first identified in Ref. 12. If this happens, then the reduced costs remain unchanged after pivoting, and therefore the value of the dual objective function ($\mathbf{c}_B^T \mathbf{B}^{-1} \mathbf{b}$) does not change as well. As a result, the dual simplex algorithm may cycle. The situation is avoided by choosing a lexicographic pivoting rule, which avoids cycling. Similar to anticycling rules for the primal simplex method, the rule states that one should choose the lexicographically smallest column, found by dividing all entries in the consideration set (columns with $a_{ik} < 0$) by a_{ik} . If a tie exists between several lexicographically smallest columns, one

Figure 1. The primal and the dual feasible spaces.

should choose the column with the smallest index. The proof of the finiteness of the simplex algorithm (either in primal or dual form) when using the lexicographic rule can be found in a number of reference texts on LP such as Refs 1, 13, or 14. Besides the lexicographic rule, Bland's rule [15] (choose as entering variable the column with the smallest index that corresponds to a positive reduced cost and break ties among row candidates by favoring the row with the smallest index number) can also be easily adapted from the primal simplex algorithm and implemented in the dual simplex.

Degeneracy. Another issue that could appear while implementing the algorithm is dual degeneracy. Dual degeneracy appears whenever there are more than m reduced costs that are 0; that is, there exists at least a nonbasic variable with reduced cost equal to zero. Since cycling and degeneracy are somewhat related, practical implementations of the dual simplex algorithm try to resolve both issues simultaneously, if possible (see, for e.g., the COIN-OR (COmputational INfrastructure for Operations Research (www.coin-or.org)) project that provides, among other things, open source implementations of simplex algorithms. A good overview of the project can be found in Refs 16 and 17).

Finding an Initial Basic Dual Feasible Solution. As we have mentioned in the outline of the dual simplex algorithm, the algorithm must start with a basic dual

Table 4. Finding a BDFS - Initial Tableau

*Pivoting element.

feasible solution (BDFS), which sometimes is not readily available. Assuming that in the primal problem, the initial basis is given by the first m columns, a dual feasible basis can be constructed by adding the constraint $\sum_{j=m+1}^n x_j \leq M$ to the primal problem. Then, let the leaving variable be the slack measure associated with this constraint, and let the entering variable be the one corresponding to the maximum reduced cost. After the pivot, either the new basis is dual feasible and thus the dual simplex can commence, or the primal problem is optimal, or the primal is unbounded (see Ref. 11 for additional discussions as to why one of these outcomes must happen).

Table 6. Finding a BDFS – Basis Identification

	z	x_1	x_2	x_3	x_4	x_5	x_6	RHS
z	1	0	-4	0	-6	0	-5	$-5M$

x_6	0	0	1	0	0	0	1	0	1
x_7	0	0	0	1	0	0	0	1	1

Example [Finding a BDFS [11], p. 277]. Consider the following tableau (Table 4), which we want to solve using dual simplex.

To get a dual basic feasible solution, we add the artificial constraint $x_2 + x_3 + x_4 \leq M$ to the problem. The slack of this constraint is x_6 , and the resulting tableau is as given in Table 5.

In the next step, x_6 leaves the basis, and x_3 enters (the maximum reduced cost is 5). The new tableau (Table 6) is dual feasible (but not primal feasible—notice the negative value of x_5).

While intuitively easy, this method is superseded in practical implementations by dual phase 1 algorithms. For an extensive review of dual phase 1 methods, see Ref. 18.

Selection Rules

From an implementation perspective, two important decisions that are quintessential to the practical performance of the dual simplex algorithm are the proper choices for the entering variable (also known as the *pricing* step) and the exiting variable (the *minimum ratio test* step). For a relatively long period of time, from the late 1950s until the early 1990s, the dual simplex was relatively ignored in practice, due to the

perception that it would not outperform the primal simplex algorithm. The last important theoretical contribution from the 1950s is Wagner’s adaptation of the dual simplex for bounded variables [19]. However, as the understanding of the structure of LP problems grew, it has become increasingly obvious that there exist classes of programs for which the primal simplex method is better, and other types of problems that tend to be better solved by the dual simplex [20]. Forrest and Goldfarth [21] and Fourer [22] helped in changing the perception about the dual simplex algorithm, by devising clever pricing techniques (steepest edge) and better ratio tests (bound flipping ratio test), that boost the dual simplex performance over its primal counterpart. Separately, Ref. 23 generalized the two-phase primal simplex algorithm to its dual counterpart. An excellent survey of the progress made with respect to the practical implementation of the dual simplex algorithm can be found in Ref. 24. Further breakthroughs emerged with the advance of parallelized implementations of the dual simplex [25].

APPLICATION OF DUAL SIMPLEX: INTEGER PROGRAMMING

One of the most important applications of the dual simplex is in large-scale optimization, particularly large-scale mixed integer programming. Traditionally, if the relaxation of a general mixed integer programming problem does not satisfy the original integrality requirements, then some mixture of variable branching and addition of valid inequalities occurs, until the branch-and-bound/cut/price implementation converges to the optimal solution (assuming it exists). Notice that branching on a fractional variable creates

Table 8. Optimal Tableau for LP Relaxation of Knapsack Example

	z	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	RHS
z	1	0	0	0	$-4/3$	$-1/3$	$-1/3$	0	0	$-19/3$
x_2	0	0	1	0	0	0	1	0	0	1
x_1	0	1	0	0	0	1	0	0	0	1
x_7	0	0	0	0	$-1/3$	$1/3$	$2/3$	1	0	$2/3$
x_3	0	0	0	1	$1/3$	$-1/3$	$-2/3$	0	0	$1/3$
x_8	0	0	1	1	0	0	0	0	1	1

two subproblems, each of which has an additional constraint—a bound on the branching variable, which destroys the primal feasibility of the original problem. Similarly, the addition of a valid inequality to the problem breaks primal feasibility. However, in the dual space, the problem remains feasible, since the addition of a row to the primal is equivalent to the addition of a column to the dual. If the added column is nonbasic, the dual basis can be used to continue the optimization via dual simplex, without the need to recompute and refactor a new basis (both of which are time intensive operations). This hot-starting feature makes the dual simplex very attractive for large-scale optimization projects. We illustrate this property with the following knapsack example.

Example [Valid Inequalities and Dual Simplex]. Consider the following knapsack problem:

$$\begin{aligned}
 \max \quad & 2x_1 + 3x_2 + 4x_3 \\
 \text{subject to:} \quad & x_1 + 2x_2 + 3x_3 \leq 4 \\
 & x_1, x_2, x_3 \text{ binary}
 \end{aligned}$$

The initial tableau for the relaxation is as given in Table 7.

After several iterations we obtain the final optimal tableau (Table 8) for the LP relaxation.

The solution is $x_1 = x_2 = 1, x_3 = 1/3$. This solution does not satisfy the binary requirements. On the other hand, notice that x_2 and x_3 cannot be simultaneously equal to 1 in the optimal solution, as that would violate the knapsack constraint. Therefore, the inequality $x_2 + x_3 \leq 1$ is valid for the original knapsack problem, and can be added to the previous tableau yielding Table 9.

Subtracting row 1 and row 4 from row 5, in order to get $\mathbf{I}_5$ as basis, yields a dual feasible solution (notice that row 5 has a negative RHS, rendering the solution primal infeasible). Dual simplex leads to optimality after one pivot (Table 10).

The solution is $x_1 = x_3 = 1, x_2 = 0$. Since this set also satisfies the binary requirements, it must be optimal to the original knapsack. The value of the objective function is $z = 6$.

CONCLUSIONS

Modern advances in LP theory establish the use of the dual simplex algorithm as a powerful optimization tool. While

the performance of the dual simplex was originally considered to lag behind that of its most popular primal variant, the dual simplex is widely used today in practice. One of the more popular applications of the algorithm includes large-scale mixed integer programming, where row additions break primal feasibility, but typically, dual feasibility remains intact. The dual simplex is also used as a *de facto* LP solver, since research has identified [20] many classes of problems where the application of the dual algorithm outperforms the performance of its primal counterpart. All these interesting properties of the method, coupled with the fact that linear optimization is a fundamental topic in operations research, ensure that advances in this area will continue to be positioned at the forefront of the discipline.

Many important economic problems have been studied with the tools of auction theory and mechanism design more generally. Much of the literature, however, studies a static, one-time decision. In many problems of interest, more than a single decision needs to be made; rather, a sequence of decisions needs to be made. These decisions often depend crucially on the dynamic aspects of the environment. For example, in the classical airline revenue management problem, an airline must decide how to price seats on a flight in response to its changing inventory as well as to the evolution of the customer base. A search engine must choose how to allocate its advertising inventory in response to changing search queries and advertiser budgets. Network capacity (either bandwidth or computational resources) needs to be dynamically reallocated in response to the arrival of new computational tasks of varying priority. Private and public procurement agencies must decide how to assign new contracts in response to the changing experiences, competencies, and availabilities of contractors.

The theory of auctions and mechanism design has been extremely successful in tackling a wide variety of problems. Unfortunately, solutions to static problems often do not translate directly to dynamic settings. Consider, for instance, the standard second-price auction for a single object with private values. Buyers are asked to submit bids for

the good, which is then allocated to the highest bidder. This winning bidder then pays the second-highest of the submitted bids. As first demonstrated by Vickrey [1], it is a (weakly) dominant strategy for buyers to bid their true values. Thus, the object is allocated efficiently: the buyer who values the object the most receives it.

In a dynamic setting, however, the second-price auction need not retain its desirable properties. The following example is illustrative. Suppose that there are two objects to be allocated: use of a production facility today and use of that same facility tomorrow. Today, two perfectly patient buyers wish to make use of the facility, the first valuing that use at \$100 and the second valuing it at \$75. A third buyer who will arrive tomorrow values use of the facility at \$50. If a second-price auction is used in each period and the buyers bid truthfully, then the first buyer will win in the first period at a price of \$75, and the second buyer will win in the second period at a price of \$50. On the other hand, suppose that the first buyer instead bids \$60 in the first period and truthfully in the second. She will then lose in the first period, but win in the second and pay a price of \$50, below what she otherwise would have paid. Thus, bidding one's value need not be an optimal strategy in a sequence of second-price auctions.

Notice that in the above example, despite the lack of truthful behavior by the bidders, the outcome is still efficient. As we will discuss later, this need not always be the case. In a more general setting when buyers are uncertain about the arrival time and willingness-to-pay of each of their competitors, Said [2] demonstrates that the second-price sealed-bid auction is often incapable of yielding an efficient outcome, even when bidders are forward-looking and fully rational. Thus, in order to achieve desirable outcomes in dynamic settings, we must move beyond tools that are best suited to static environments.

This is precisely the aim of the recent (and growing) literature on dynamic mechanism

design. We survey this literature, categorizing it by the nature of the dynamics involved. In particular, we examine two strands of literature: one in which the population of agents changes over time, but their private information is fixed; and the other in which the population of agents is fixed, but their private information changes over time. We will further divide these two categories into those papers whose aim is achieving efficient outcomes and those whose aim is achieving revenue-maximizing outcomes.

A DYNAMIC POPULATION WITH FIXED INFORMATION

We begin by exploring the possibility of implementing desirable outcomes when faced with a dynamic population whose private information is fixed. In the course of our discussion, we will examine some of the problems that arise in such settings and how they differ from those found in static, one-shot models. Note that all the models and papers we discuss assume private values.

Maximizing Social Welfare

Efficiency in the Face of Arrival and Departure Dynamics. Parkes and Singh [3] develop a framework for studying sequential allocation problems in a dynamic population setting. In their world, various subsets of agents are present at various times. In particular, each agent has an arrival time and a departure time, and has a utility function for decisions made while she is present. What makes the problem especially difficult is that the decision maker (and mechanism designer) does not know any of this information—the designer must incentivize the agents to reveal that information.

Despite this difficulty, Parkes and Singh are able to construct a mechanism (the “online VCG” mechanism) which generalizes the Vickrey-Clarke-Groves mechanism from static environments and implements the efficient outcome. Their mechanism is a direct revelation mechanism in which buyers report their private information upon arrival to the mechanism. Given these reports, the mechanism carries out an efficient policy.

In order to enable the truthful revelation of private information, the mechanism chooses transfers that align agents’ incentives with those of a benevolent social planner. Similar to how the static VCG mechanism sets transfers equal to the externality that an agent imposes on other agents, the online VCG mechanism sets transfers equal to the *expected* externality that an agent imposes. This expected externality takes into account each agent’s impact on the other agents currently present *as well as* on agents that may arrive in the future.

We should note, however, that *unlike* the static VCG mechanism, this truthful reporting is *not* a dominant strategy, as the calculation of expected externalities depends upon the truthful reporting of all other agents. If, instead, an agent believes that agents in the future are not reporting truthfully, it may be in her best interest to misreport her true type.

Efficient Sequential Assignment with Impatient Buyers. In related work, Gershkov and Moldovanu [4] examine the allocation of a finite set of heterogeneous durable goods to a dynamic population of randomly arriving buyers. Crucially, the buyers in this setting are impatient—they wish to purchase an object immediately upon their arrival on the market. Moreover, these buyers share a common ranking of the various objects. In this setting, objects are durable while buyers are impatient. This implies that the relevant trade-off is between allocating an object to a buyer at the current time and the option of assigning it to a buyer in the future who might value it more. In a complete information setting, the efficient dynamic allocation policy was first characterized by Albright [5]. This policy prescribes an ordered partition of the set of possible valuations at each possible time. Agents with values in the highest element of the partition receive the best available object; agents in the second-highest element receive the second-best remaining object, and so on. These intervals may depend upon the time of an agent’s arrival or on the set of remaining objects.

Gershkov and Moldovanu [4] show that this efficient policy is, in fact, implementable in the presence of incomplete information

about the valuations of arriving buyers. Since buyers are impatient, there is no loss of generality in considering direct revelation mechanisms where each buyer reports her type to the mechanism designer upon her arrival to the market. Each buyer is charged the *expected* externality that he/she imposes on future agents, where expectations are taken with respect to the arrival process and the valuations of future agents. This implies that each agent's net utility is exactly equal to his/her expected marginal contribution to the social welfare, conditional on the information available at the time of her arrival—essentially, the efficient mechanism is a dynamic Vickrey-Clarke-Groves mechanism like the Parkes and Singh [3] online VCG mechanism discussed above.

Efficient Auctions with Dynamic Populations. In a closely related recent work, Said [2,6] examines the allocation of a sequence of indivisible goods to a dynamic population of buyers. In this setting, patient buyers demand a single unit of perishable homogeneous goods (such as computational time on a central computing facility, or capacity in a production line). These buyers arrive at random times to the market, and have private valuations, which are drawn independently and identically from a given distribution.

While a variant of the online VCG mechanism of Parkes and Singh [3] may be used in order to achieve an efficient allocation of objects to buyers, these mechanisms are direct revelation mechanisms, requiring buyers to report their values to the mechanism upon their arrival to the market. In practice, however, direct revelation mechanisms may be difficult to implement or undesirable due to privacy or complexity concerns.

Therefore, *indirect* auction mechanisms are often useful. In standard static settings, the canonical auction for efficiently allocating goods to buyers is the sealed-bid second-price auction. This mechanism is the auction analogue of the Vickrey-Clarke-Groves mechanism, allocating the object to the buyer who submits the highest bid and charging her a price equal to the second-highest bid. Said [2] shows that, when selling a sequence of objects, one in each period, to a stream

of buyers who arrive at random times, the sealed-bid second-price auction is no longer efficient.

In a sequential auction, buyers have an “option value” associated with losing in a particular auction, as losing bidders have the possibility of winning in a future auction. The value of this option to a particular buyer depends on his/her expectations of the prices he/she may have to pay in the future. This is, of course, dependent upon the private information and values of other competitors. Thus, despite the fact that buyers' values for an object do not depend upon the information of their competitors, the dynamics of a sequential auction market *generate interdependence* in (option) values.

This interdependence implies that a standard second-price sealed-bid auction does not reveal sufficient information for the determination of buyers' option values. In contrast, the ascending (or English) auction is a simple *open* auction format that does allow for the gradual revelation of buyers' private information. As buyers drop out of each auction, they indirectly reveal their private information to their competitors, who are then able to condition their current-period bids on this information. Moreover, this process is repeated in every auction in every period. This allows newly arrived buyers to learn about their competitors without being privy to the detailed events of the previous periods, thereby allowing for an efficient outcome.

Maximizing Revenue

Before discussing revenue-maximizing dynamic mechanisms and auctions, it will be helpful to briefly review the (standard) results for static environments. In a static setting, in which all buyers are present simultaneously, Myerson [7] solves the optimal mechanism design problem in the following manner:

1. Incentive compatibility requires that the allocation rule be monotone; that is, buyers who report a higher type must have a greater probability of receiving an object.
2. Given a monotone allocation rule, the corresponding payment rule is pinned

down (up to a constant) via the revenue-equivalence principle. When the goal is maximizing revenues, the constant can be determined via individual rationality constraints.

3. Combining these two observations, the revenue-maximization problem can be transformed to the problem of maximizing “virtual” surplus—the surplus from allocating objects less the information rents that must be paid in order to induce truthful revelation of types.

Thus, instead of maximizing the sum of agents’ values as in the case of efficient mechanism design, Myerson’s insight is that revenue-maximization is equivalent to maximizing the sum of agents’ *virtual* values, where the virtual value of a buyer is given by the difference between his/her true value and the information rents necessary for inducing truth-telling. An optimal allocation rule, therefore, allocates objects to the buyers with the highest nonnegative virtual values—precisely those with the most favorable trade-off between surplus and information rents.

When buyers are *ex ante* symmetric and the distribution of values is such that virtual values are nondecreasing then this optimal allocation rule is monotone in values. Thus, incentive compatibility is achieved “for free” and the optimal auction corresponds to a second-price auction with an appropriately chosen reserve price. If, on the other hand, virtual values are not increasing, then the monotonicity constraint may be satisfied via a procedure termed “ironing” which pools some types of agents and randomizes among them. Thus, in the static setting, increasing virtual values is sufficient for revenue-maximization to correspond to maximizing virtual surplus.

Revenue-Maximization in the Face of Arrival and Departure Dynamics. Returning to the setting of arrival and departure dynamics, Pai and Vohra [8] present what may be thought of as the revenue-maximizing counterpart to the efficient online VCG mechanism of Parkes and Singh [3]. Here, a seller with a fixed, finite supply of a

homogenous good faces a population of potential buyers with unit demand who arrive and depart over the course of a finite time horizon. As in Parkes and Singh, the times at which each agent arrives and departs from the market are her private information, as is her valuation for an object. Agents’ types are assumed to be independent draws from a common distribution. The seller wishes to design an incentive-compatible direct mechanism in order to maximize his revenues.

The challenge then is to extend Myerson’s notion of a virtual value in order to account for the additional privately known arrival and departure times. Moreover, even if such a virtual value is defined, the multidimensional nature of the private information implies that we must also find an appropriate notion of monotonicity in order to guarantee incentive compatibility.

Some care must be used when considering direct revelation mechanisms in this setting with random arrival and departure times. In particular, note that buyers cannot make reports before their arrival or claim to depart after their true departure time (see Green and Laffont [9] for more on restricted mechanisms and the revelation principle). Taking this into account, Pai and Vohra use an appropriate formulation of the revelation principle of Myerson [10] to restrict attention to mechanisms that allocate to buyers, if at all, only in the period of their departure. They use the incentive compatibility constraints to show that the optimal allocation rule must be monotone in valuations, holding entry and exit times fixed. Moreover, incentive compatibility also requires that the allocation rule be monotone in entry and exit times. In particular, a buyer who arrives earlier or departs later should have a greater probability of receiving an object. (Thus, buyers are incentivized to report the greatest possible window of opportunity.)

Making use of the conditions imposed by incentive compatibility, Pai and Vohra [8] are able to arrive at a notion of virtual valuation similar to that of Myerson [7], except that information rents vary across reported arrival and departure times. Thus, in each period, the seller compares the

virtual surplus from allocating an object to a departing agent to the expected virtual surplus of waiting an additional period. A departing agent will receive an object only if the former is greater than the latter. However, unlike the setting of Myerson, increasing virtual values are no longer sufficient for such an allocation rule to be optimal, but instead additional “ironing” may be necessary: the optimal mechanism may need to occasionally withhold an object despite a lower future expected virtual surplus.

Optimal Sequential Assignment with Impatient Buyers. Recall the relationship between Parkes and Singh [3] and Gershkov and Moldovanu [4] discussed earlier. An analogous relationship exists between the work of Pai and Vohra [8] and Gershkov and Moldovanu [11]. This latter work considers the problem of revenue-maximization in a setting with a dynamic population of impatient buyers. As in the paper discussed earlier, a seller has a finite set of heterogeneous durable goods that he wishes to sell to randomly arriving buyers who wish to purchase an object immediately upon their arrival to the market. (In a setting with homogeneous durable goods and patient buyers arriving stochastically, Gallien [12] shows that when the distribution of buyer inter-arrival times has an increasing failure rate, the optimal mechanism allocates goods to buyers only upon their arrival. There, as Board [13] also shows in a related discrete-time setting, the seller may behave as though buyers are impatient.)

As in Pai and Vohra [8], there is a dynamic trade-off that is introduced by the arrival process of buyers. In particular, when considering allocating an object to a particular agent, the seller must consider the opportunity cost of allocating that object to future agents. However, the problem here is (in some ways) simpler as buyers no longer have multidimensional types. Since buyers are impatient, there is no need to consider incentives for revealing arrival or departure times—the only dimension of private information is the private value that buyers have for each object.

Thus, the authors are able to prove that (as in the case of the efficient policy) any incentive compatible policy must take the form of an ordered partition of possible valuations at each point in time. This follows directly from the fact that short-lived agents’ decision problems are static, and so static insights about incentives apply directly. Thus, agents with values in the highest element of the partition receive the best available object; agents in the second-highest element receive the second-best remaining object, and so on.

The next step in the characterization of the revenue-maximizing dynamic mechanism is to determine the revenue generated by any particular incentive compatible policy. The problem faced by the seller upon the arrival of any particular agent can then be translated into a static problem. More specifically, the seller must decide between allocating an object to the newly arrived agent and obtaining the revenue generated by ignoring that agent’s arrival and proceeding with the (given) policy. This is the same as the problem faced by a standard (static) revenue-maximizing monopolist selling a single object, when the cost of that object is given by the salvage value of the inventory (which corresponds to the expected future revenues from the dynamic policy). It is possible, by working backwards from the case of a single-object inventory, to determine the optimal partition of the valuation space for each possible inventory and point in time. The revenue-maximizing prices that correspond to these cutoffs are then derived via revenue-equivalence.

Optimal Auctions with Dynamic Populations. In a complementary setting, Said [2] explores the properties of revenue-maximizing dynamic auctions. Instead of durable goods and impatient buyers, he examines the assignment of a sequence of perishable goods to a population of patient buyers. The buyers arrive to the market at random times and remain until they receive an object. Since their values for the objects are private information, incentives must be provided for information revelation in order to achieve an optimal allocation.

In this setting, the seller and buyers discount the future with a common discount

factor $\delta \in (0, 1)$. This implies that even though objects are assumed to be individual units of a homogeneous good, from the perspective of any individual buyer, they are differentiated products. To make this clear, consider a buyer i with value v_i who is present on the market at some time t . If this buyer receives an object in period t , she receives a payoff of v_i . However, if she anticipates receiving an object in period $t + 1$, then her expected payoff is δv_i . Thus, she does not value the two objects identically.

This alters the appropriate condition for incentive compatibility. Recall that in static settings with single-unit demand, incentive compatibility requires that increasing a buyer's type should increase her probability of receiving an object. In this dynamic setting with single-unit demand, incentive compatibility instead requires that increasing a buyer's type should increase her probability of receiving an object sooner. This characterization of incentive compatibility allows for the derivation of a revenue-equivalence theorem for this setting, which implies that revenue-maximization can be achieved (in the Myersonian tradition) by maximizing the virtual social surplus.

Said [2] shows that applying a variant of the online VCG mechanism discussed earlier to virtual values maximizes revenues. Instead of providing each buyer with a net utility equal to her expected marginal contribution to the social surplus, Said's mechanism leaves each buyer with a net utility equal to her expected marginal contribution to the *virtual* surplus. Moreover, if an indirect mechanism is desired, the earlier discussion on efficient but indirect mechanisms remains relevant—instead of a sequence of second-price sealed-bid auctions with an optimally chosen reserve price, a seller should use a sequence of ascending auctions with that same reserve price.

If objects are durable instead of perishable, the recent work of Board and Skrzypacz [14] provides a characterization of the optimal dynamic auction. As before, the revenue-maximizing direct mechanism applies an efficient mechanism to virtual values. This implies that there is a constant cutoff value below which objects are not

allocated, and the object is allocated to the buyer with the highest valuation exceeding that cutoff. This cutoff is determined by a simple one-period-look-ahead policy which requires the seller to be indifferent between selling to the cutoff type in the current period and waiting an additional period for new buyers to arrive.

With a single durable object to be allocated, these cutoffs are constant in all but the final period, and then drop in that period to the static monopoly price. This implies that buyers either buy immediately upon their arrival or wait for the “fire sale” in the final period. If the seller wishes to use an indirect mechanism in order to implement this optimal policy, Board and Skrzypacz show that a sequence of second-price auctions with deterministically declining reserve prices is optimal. These reserve prices are chosen such that the cutoff type is exactly indifferent between purchasing in the current period and waiting an additional period. The reserve price must be declining so as to compensate this cutoff-type buyer for the losses due to discounting *as well as* for the possibility of new competition arriving in future periods. It follows that the reserve price must fall at a rate faster than the discount rate.

A FIXED POPULATION WITH DYNAMIC INFORMATION

The preceding section examined dynamic auctions and mechanisms for settings in which there is a dynamic population with static, fixed types. A large and important class of problems, however, does not fit within this framework. Consider, for instance, the case of sponsored search, where search engines sell advertising slots alongside “organic” search results. In this setting, advertisers who are interested in a particular keyword may revise their estimates of the value of an advertisement based on their experiences over time. The natural question that arises in such a setting is how to design mechanisms and auctions in order to properly account for the changing private information.

We first consider the case of implementing socially efficient outcomes in environments

with dynamic information. The mechanisms we examine generalize insights from static settings to enable the truthful revelation of changing private information in a dynamic environment. We then turn to the objective of maximizing revenues and discuss the recent work in that area. As in the previous section, we focus on private value environments.

Maximizing Social Welfare

Dynamic Pivot. Bergemann and Välimäki [15] consider the problem of providing incentives for truthtelling and satisfying participation constraints in an efficient mechanism. They consider a general infinite-horizon dynamic model in which participants observe a sequence of private signals over time, and a sequence of decisions must be taken in response to these signals. The distribution of signals may depend on previously observed signals or decisions; however, these signals are independent across agents (conditional on observables).

Bergemann and Välimäki propose the Dynamic Pivot Mechanism. This mechanism is the natural generalization of the static Vickrey-Clarke-Groves mechanism to a dynamic environment. Recall that VCG-like mechanisms incentivize truthtelling by making efficient decisions and choosing transfers such that each agent's payoff is equal to the total social surplus. By varying the transfers to each agent in a way that does not depend on her own report, we obtain an entire set of efficient mechanisms. The "Pivot" mechanism (which is often considered the canonical VCG mechanism) is the member of this class that subtracts from each agent's transfer the surplus that the other agents could have achieved in her absence; that is, it chooses transfers equal to the externalities imposed on the rest of the system so that each agent's net utility is equal to her marginal contribution to the social welfare.

The key insight of Bergemann and Välimäki [15] is that in a setting with dynamic private information, incentives for truthtelling and efficiency may be guaranteed by choosing payments in each period to be equal to the *flow* externalities. More precisely, the externality that an

agent's report in any given period imposes on all other participating agents may be decomposed into a current period effect and a future (expected) effect. By committing to a sequence of transfers equal to the sequence of current-period externalities, the mechanism designer or social planner is able to give each buyer a flow payoff equal to her flow marginal contribution to the social welfare. Therefore, each agent's expected discounted payoff, looking forward from any period, is equal to her *total* marginal contribution to the social welfare (again, starting at that point). This property (which figured prominently in Bergemann and Välimäki [16,17] in the construction of dynamic first-price auctions in a complete information setting) implies that, in each period, all participating agents internalize the impact of their current reports on others, thereby aligning their incentives with those of the efficiency-minded planner.

Cavallo, Parkes, and Singh [18] develop a mechanism similar to the Dynamic Pivot Mechanism in a setting with agents, whose type evolution follows a Markov process. In Cavallo, Parkes, and Singh [19], they extend dynamic VCG to settings in which buyers are "periodically inaccessible" and are unable to make reports (as in the case, for instance, of a network setting where connectivity is sometimes lost). Moreover, Cavallo [20] has shown that the dynamic pivot mechanism is also similar to its static VCG counterpart, in that it achieves greater revenue than any other possible efficient (dynamic) mechanism. Therefore, in settings where the mechanism designer is concerned with both revenue and efficiency, the use of the dynamic pivot mechanism may provide a partial resolution to the conflict among the two.

Efficiency and Budget-Balance. Athey and Segal [21] consider a similar setting to that of Bergemann and Välimäki [15]; however, they are also interested in finding an efficient mechanism that is budget-balanced—that is, a mechanism that requires no external subsidies. In order to do so, Athey and Segal propose the efficient "Team Mechanism." This mechanism induces truthfulness by providing a transfer to each agent, in each

period that is equal to the sum of utilities of all the other agents in that period. Thus, in the same manner as the Dynamic Pivot Mechanism (as well as the static VCG mechanism), such a transfer scheme ensures that each agent is a residual claimant for the total social surplus.

As the Team Mechanism is not budget-balanced, Athey and Segal modify it in a generalization of the classic AGV mechanism of d'Aspremont and Gerard-Varet [22]. The AGV mechanism, in a static environment, permits truthtelling by charging agents transfers equal to the “expected externality,” their reports impose on others. However, the value of these transfers are dependent upon agents’ beliefs, and in a dynamic setting, these beliefs may be evolving over time and may, in fact, be manipulated by other agents. In order to avoid such manipulations, Athey and Segal construct the “Balanced Mechanism,” which takes advantage of the dynamic setting using the *changes* in the expected present value of other agents’ utilities. By doing so, agents continue to internalize the expected externality that they impose upon others. Moreover, these new transfers are not manipulable by other agents, thereby allowing for budget-balance while also implementing efficient outcomes.

One should note that, as with the static AGV mechanism, it may be impossible to both balance the budget and also satisfy participation constraints. Although the Balanced Mechanism satisfies *ex ante* participation constraints (so that all agents wish to participate in the mechanism at the time of contracting), it differs from the Dynamic Pivot Mechanism of Bergemann and Välimäki [15], in that some agents may wish to exit the mechanism after some histories. Athey and Segal [21] show, however, that if the time horizon is infinite and agents are sufficiently patient, then it is possible to satisfy these “periodic” participation constraints.

Maximizing Revenue

Contracting with Dynamic Information. In many environments, buyers learn about their demand over time. In an important contribution, Courty and Li [23] consider optimal

dynamic contracts for such a setting. In their model, buyers have private information about the future distribution of their valuations for the seller’s object. Subsequently, these buyers then privately learn the realization of their value. The monopolist could choose to wait until buyers learn their realized values and then charge the standard monopoly price. Surprisingly, by requiring the buyers to reveal their private information sequentially, the seller is able to extract additional surplus. Instead of “screening” buyers once after all private information is acquired, revenue-maximization requires screening them twice with a set of contingent contracts.

As in a standard static mechanism design problem, revenue-maximization corresponds to allocating to the buyers with the highest virtual values, thereby maximizing virtual surplus. Since buyers’ initial types influence their ultimate value for the good, the concept of a virtual value in this context must take into account this influence. Specifically, the information rents “paid” to buyers in the first period (at the time of contracting) must account for the informativeness of initial types about future types: the more informative the initial type about the future realization, the greater the information rents that must be paid. Since incentive compatibility requires monotonicity in the allocation rule, this implies that distortions away from efficiency are correspondingly increased.

Eső and Szentes [24] consider a closely related setting in which buyers have an initial estimate of their valuation, and the seller is able to control buyers’ acquisition of additional refined information. Specifically, the seller is able to choose whether to allow buyers to receive additional signals that are correlated with their private information. They show that in the optimal revenue-maximizing mechanism, the seller releases all the additional private information that he is able to. Moreover, his revenue in this case is as large as the revenue he would be able to achieve if he could observe this information—quite surprisingly, buyers gain no advantage from this additional information and receive no additional information rents when the seller is able to control

the flow of information. Roughly speaking, by using a more sophisticated dynamic mechanism, the seller pays information rents to buyers in the initial period, in order to incentivize the revelation of their initial private information, but subsequently extracts all remaining potential surplus.

In a particular application, Eső and Szentes [24] show how such a mechanism would operate. Suppose buyers' initial private information is a noisy signal of their value, and that they can then receive additional information that informs them of their actual value. The optimal mechanism in this case is a "handicap auction" in which buyers can purchase an advantage in a second-stage efficient auction. More concretely, each buyer purchases a price premium from the seller (where a smaller premium costs more), and then in the second period (after the revelation of additional information) the buyers engage in a modified second-price sealed-bid auction in which the winner is required to pay her purchased premium in addition to the second-highest bid. The seller is able to extract additional revenue by inducing buyers with higher expected values to purchase smaller handicaps for the second-stage auction.

Dynamic Incentives and Revenue Equivalence. The recent contribution of Pavan, Segal, and Toikka [25] generalizes the results of Myerson [7] and Baron and Besanko [26] to a general dynamic setting. In particular, they characterize incentive compatibility and revenue in multiperiod settings with dynamic private information. The primary challenge in such settings is an element of multidimensionality. Instead of the single dimension of potential misreports possible in a traditional static mechanism design problem, agents may be able to misrepresent multiple "pieces" of information, possibly choosing misreports contingent on her previous private information.

The key step in their analysis is the development of a "dynamic payoff formula" which expresses the derivative of an agent's expected payoff (and hence the seller's revenue) in an incentive compatible mechanism with respect to her private information.

This formula summarizes the local incentive compatibility constraints that a mechanism designer must respect. Pavan, Segal, and Toikka demonstrate the manner in which this dynamic payoff formula relies on incentive compatibility not only in a given period, but also in all future periods; therefore, they are able to capture not just the impact of a change in an agent's private information on her current-period payoffs, but also the influence on future private information.

This machinery yields a dynamic revenue-equivalence theorem: the expected revenue in any dynamic mechanism is determined entirely (up to a constant) by the allocation rule. Moreover, the expected revenue in an incentive compatible mechanism is given exactly by the expected virtual surplus generated by that mechanism, where agents' virtual values (as in Baron and Besanko [26]; Country and Li [23]; and Eső and Szentes [24]) depend upon the informativeness of current-period private information on future private information. Thus, Pavan, Segal, and Toikka [25] provide necessary conditions (and some sufficient conditions) for incentive compatibility and a general methodology for revenue-maximization in dynamic settings.

One limitation of the generality of that work, however, is the difficulty in establishing general sufficient conditions for the incentive compatibility of a mechanism that are easily verified. In a complementary paper, Pavan, Segal, and Toikka [27] use an approach pioneered by Eső and Szentes [24] to represent an agent's future-period types as a function of their first-period type and a random "shock" that is independent of the first-period type. This approach allows the identification (under slightly different assumptions) of conditions for incentive compatibility in infinite-horizon settings.

Despite this, however, sufficient conditions for incentive compatibility often need to be determined on a case-by-case basis for various models. One such determination may be found in Kakade, Lobel, and Nazerzadeh [28], which sets out a model of sponsored search auctions in which advertisers learn about the efficacy of their advertisements over time. Their model combines elements of both private information and statistical

learning. In particular, private information evolves according to a multiarmed bandit process (Deb [29] also considers a similar setting). The authors also impose “separability” conditions on the stochastic process governing the evolution of private information (specifically, that it is a Markov process) along with additive or multiplicative separability of buyers’ utility functions in their initial private information and future private information. These conditions are, in fact, sufficient conditions under which the maximization of virtual surplus by using an efficient algorithm (the Gittins index policy) applied to virtual values maximizes revenue.

In a related setting, Battaglini [30] examines an infinite-horizon model and characterizes the revenue-maximizing long-term contract of a monopolist facing a buyer whose value follows a two-type Markov process. This optimal contract is nonstationary; however, this contract (eventually) converges over time to the efficient supply. A crucial insight (that follows from the work of Pavan, Segal, and Toikka) is that, in an irreducible two-type Markov process, the impact of changing the current-period type vanishes in the long run—the current-period type is almost completely uninformative about types in the distant future. Therefore, distortions away from the efficient contract diminish in the long run, regardless of the degree to which types are persistent.

FURTHER READING

A large body of work has developed in this area. For further reading and examples of dynamic auctions and mechanisms for settings with changing populations and private information, the curious reader may wish to consult, among others, Akan, Ata, and Dana [31]; Aviv and Pazgal [32]; Cavallo [33]; Doepke and Townsend [34]; Gershkov and Moldovanu [35]; Kittsteiner and Moldovanu [36]; Parkes [37]; Satterthwaite and Shneyerov [38]; Shen and Su [39]; Talluri and van Ryzin [40] [Chapter 6]; and Vulcano, van Ryzin, and Maglaras [41].

TRADITIONAL MODELS OF DYNAMIC OPTIMIZATION

Stochastic Programming

Information in real-life applications is often revealed in stages, forcing the manager to make decisions with only limited knowledge of the data, and to adjust his strategy as he observes the realization of random parameters such as customer demand over time. Dantzig [1] first investigated decision making under uncertainty in the 1950s, pioneering the field now known as stochastic programming (SP). This methodology assumes that parameters are random but obey a known discrete distribution and that the decision maker minimizes (or maximizes) the expected objective value over the possible scenarios. The most frequent setup has two stages, with two groups of decision variables: *here-and-now* (or first-stage) variables, which represent decisions made before the manager can observe the resolution of the uncertainty; and *wait-and-see* (or second-stage) variables, which represent recourse actions. The SP problem is linear but of potentially very large size, motivating the use of structure-specific solution methods. The structure here is that the constraints either connect first-stage decision variables with each other, or first-stage decision variables with second-stage decision variables for a specific scenario, but never second-stage decision variables for different scenarios. Such a structure is said to be L-shaped because of the position of the nonzero elements in the coefficient matrix. The second-stage problem, formulated for

the given first-stage variables, is called the *recourse problem*. It can be shown to be convex and piecewise linear. The main algorithm used to solve this problem relies on generating pieces of the recourse function as needed, which can be interpreted as a delayed constraint generation algorithm. The reader is referred to Birge and Louveaux [2], Kall and Wallace [3], Prékopa [4], and Ruszczyński and Shapiro [5], and the references therein for a wide-ranging treatment of SP.

If recourse decisions are required to be integer (which is called SP with integer recourse), the integrality constraints increase the complexity of the second-stage problem significantly and the master problem becomes very hard to solve. Stochastic integer programs (where some variables are forced to be integer, in the first and/or second stages) are computationally intractable. Algorithms used to solve these problems include variants of the L-shaped method based on Benders decomposition [6–9] and branch-and-bound [10], among others.

Drawbacks. Under the assumption that the stochastic parameters are independently distributed, Dyer and Stougie [11] show that the two-stage SP problems are NP-hard. Furthermore, the number of scenarios grows exponentially with the number of parameters when the latter are independent, creating tractability issues. (For instance, a retailer considering 15 independent products with demand for each taking three possible values would need to generate over 14 million scenarios.) Moreover, it is often difficult to estimate probability distributions accurately. Even when the distributions of random parameters for past time periods can be estimated with a high degree of precision using historical data, these distributions might differ from future ones in unpredictable ways due to changing conditions. The difficulties faced by two-stage SP are compounded in the multistage case, where multiple piecewise linear recourse functions, corresponding to different time

periods, need to be approximated by generating linear pieces as needed. Shapiro and Nemirovski [12] provide an in-depth discussion of the complexity of two-stage and multistage SP problems, and argue that multistage SP problems are, in general, intractable.

Dynamic Programming

Dynamic programming (DP) deals with multistage decision making. The key idea is that the manager behaves optimally at all time periods, which reduces the number of strategies to be considered. This is formulated in mathematical terms through a system of recursive equations known as the *Bellman equations*:

$$\begin{aligned} V_t(S_t) &= \min_{x_t \in X_t} \{C_t(S_t, x_t) + E\{V_{t+1}(S_{t+1}|S_t, x_t)\}\} \\ \forall S_t &\in \mathcal{S}_t, \end{aligned} \quad (1)$$

where $V_t(S_t)$ is the *optimal* value (cost-to-go function) associated with being in state S_t in stage t and S_{t+1} is the state at the next time period. $\mathcal{S}_t$ is the space of possible states at time t . Intuitively, the equations state that the manager will follow the optimal strategy from time $t + 1$ onward, so that the problem at time t reduces to minimizing the current costs plus the optimal costs incurred from the next time period up to the end of the time horizon.

Solving Problem (1) requires the investigation of structural properties of the value functions to guarantee global optimality. DP is most insightful when the optimal policy can be proved to have a certain structure and the decision maker only has to compute the parameters defining that policy (for instance, basestock levels in dynamic inventory management under uncertainty [13]). It is important to note that DP leads to optimal *policies*, rather than optimal numbers, so that the decision maker does not need to resolve his/her problem as time progresses and uncertainty is revealed: he/she simply implements the precomputed policy that corresponds to the state and the time period he/she is in. Because DP relies on the fact that the decision maker will act on new information

at the next stage, it is sometimes called *closed-loop optimization* (new observations are incorporated in a feedback loop), in contrast to open-loop optimization, which generates numbers rather than policies and where the problem needs to be resolved at each time period to capture new information. (An advantage of open-loop optimization is that it is much less computationally demanding.) Readers may refer to Bertsekas [13] and Powell [14] for detailed treatments of DP.

Drawbacks. Value functions need to be stored for each time period and each possible state at that time period, creating severe dimensionality challenges as the size of the state space and/or the time horizon increases. This is known as the *curse of dimensionality*, which makes DP impractical in many applications. Approximate DP attempts to overcome these shortcomings [14,15], but remains hard to implement. In addition, as for SP, it can be difficult to estimate the underlying probability distributions accurately.

In summary, there are two main issues with the traditional methods of dynamic decision making under uncertainty:

1. Probability distributions are difficult to estimate accurately.
2. Dimensionality issues arise even when the distributions of the random parameters are exactly known.

We show in subsequent sections of this article how robust optimization (RO) can address these issues.

POSSIBLE DEFINITIONS FOR ROBUST OPTIMIZATION

RO is another method that addresses data uncertainty. Unlike SP and DP, RO models uncertainty assuming that uncertain parameters belong to a bounded, convex uncertainty set. While SP minimizes expected cost (or maximize expected revenue), RO is a worst-case analysis and minimizes the maximum value of the objective over the uncertainty set. This approach was pioneered by Soyster [16] in the 1970s, although he did not

call it “robust optimization” at the time. He assumed that each uncertain parameter took values in an uncertainty *interval* and proposed an optimization model to generate feasible solutions for the worst case. Because the model led to each parameter being equal to its worst-case value, it was thought to be too conservative for implementation in business; however, the issue of solution feasibility has remained an important topic of research, which saw critical advances in the 1990s.

Scenario-Based Robust Optimization

The expression “robust optimization” became popular in the mid-1990s, when Mulvey *et al.* [17] proposed a scenario-based description of the problem data and penalized the variance of the optimal solution for any realization of the scenarios, given a certain level of risk expressed by the decision maker. This approach does not match Soyster’s and is not in line with later uses of the expression “robust optimization,” which is described below. We mention it here because of its relation to SP as well as to avoid confusion for the reader familiar with Mulvey *et al.* [17] and subsequent approaches called RO.

Consider the LP optimization model

$$\begin{aligned} \min_{x \in \mathbb{R}_1^n, y \in \mathbb{R}_2^m} \quad & c^T x + d^T y \\ \text{s.t.} \quad & Ax = b, \\ & Fx + Gy = h, \\ & x, y \geq 0. \end{aligned} \quad (2)$$

Let $\Omega = (1, 2, \dots, S)$ be the set of scenarios with p_s probability of scenario s , where each scenario $s \in \Omega$ is associated with the vector (d_s, F_s, G_s, h_s) of realizations for the uncertain coefficients. y_s is the second-stage control vector for scenario $s \in \Omega$; also, we introduce a new vector z_s , which measures the extent of the constraint infeasibility under data scenario s . The objective function $\xi = c^T x + d^T y$ becomes a random variable that takes values $\xi_s = c^T x + d_s^T y_s$ with probability p_s for $s \in \Omega$.

The robust counterpart (RC) of Problem (2) using the Mulvey–Vanderbei–Zenios framework can then be formulated as

$$\begin{aligned} \min \quad & \sigma(x, y_1, \dots, y_s) + \omega \cdot \rho(z_1, \dots, z_s) \\ \text{s.t.} \quad & Ax = b, \\ & F_s x + G_s y_s + z_s = h_s, \quad \forall s \in \Omega \\ & x, y_s \geq 0 \quad \forall s \in \Omega. \end{aligned} \quad (3)$$

The $\rho(z_1, \dots, z_s)$ term in the objective function is a feasibility penalty function, whereas $\sigma(x, y_1, \dots, y_s)$ is the optimality robustness term. (The scalar ω captures the decision maker’s trade-off between the two goals of feasibility and optimality.) If the solution is “close” to the optimal one for any realization of the scenario $s \in \Omega$, then it is referred to as *solution-robust*. If it remains “almost” feasible for any scenario realization, then it is referred to as *model-robust*. The authors suggest possible functions in their work [17] to help users define solution-robustness and model-robustness. For instance, for moderate- to high-risk decisions under uncertainty, they advocate the use of the average objective plus a constant (λ) times its variance as an appropriate solution-robustness term:

$$\begin{aligned} \sigma(x, y_1, \dots, y_s) \\ = \sum_{s \in S} p_s \xi_s + \lambda \cdot \sum_{s \in S} p_s \left(\xi_s - \sum_{s' \in S} p_{s'} \xi_{s'} \right)^2 \end{aligned}$$

An example of feasibility penalty function is

$$\rho(z_1, \dots, z_s) = \sum_{s \in S} p_s z_s^T z_s$$

where both positive and negative violations of the control constraints are equally penalized.

Mulvey *et al.* [17] apply this technique in their work to applications such as power capacity expansion, matrix balancing and image reconstruction, air-force airline scheduling, scenario immunization for financial planning, and minimum-weight structural design. Other applications include capacity expansion of telecommunication networks [18], a more in-depth look at power capacity expansion [19], and the portfolio management of callable bonds [20].

Drawbacks. This approach to RO changes the structure of the deterministic model; the robust model is no longer linear. In addition, it suffers from the same dimensionality issues encountered in SP.

Set-Based Robust Optimization

Ben-Tal and Nemirovski [21–23], El-Ghaoui and Lebret [24], and El-Ghaoui *et al.* [25] focus w.l.o.g. on uncertainty in the constraints of mathematical programming problems and define robust solutions as solutions that are feasible for the worst-case value of the parameters within an uncertainty set. They use ellipsoidal uncertainty sets and propose a tractable mathematical reformulation that turned linear programming problems into second-order cone problems, while reducing the conservatism of Soyster’s [16] approach. Furthermore, Ben-Tal and Nemirovski [26] study RO applied to conic-quadratic and semidefinite programming. The reader is referred to Ben-Tal *et al.* [27] for an overview of RO, with an emphasis on ellipsoidal sets. One drawback of that framework is that it increases the complexity of the nominal problem.

Bertsimas and Sim [28,29] and Bertsimas *et al.* [30] investigate the case where the uncertainty set is a polyhedron. Specifically, the uncertainty set consists in range forecasts (confidence intervals) for each parameter and a constraint called a budget-of-uncertainty constraint, which limits the number of coefficients that can take their worst-case value. The approach preserves the degree of complexity of the problem (the RC of a linear problem is linear) and allows the decision maker to control the degree of conservatism of the solution. Bertsimas and Sim [28] also provide a probabilistic guarantee of constraint violation. A drawback of the approach is that it adds auxiliary variables and constraints to the initial formulation. Bertsimas and Thiele [31] survey the RO literature up to 2006, especially for polyhedral uncertainty sets.

Those early works spearheaded significant research efforts on the theory and practice of RO. Bertsimas and Brown [32] provide a methodology to construct uncertainty sets within the framework of RO, using the decision maker’s risk preferences expressed

by a coherent risk measure. RO has been applied to inventory management [33,34], revenue management [35], portfolio management [36,37], telecommunications [38], among others. Notice that while RO was initially developed to address data ambiguity (i.e., uncertain parameters whose value was unknown but constant), the methodology was subsequently applied to random variables with uncertain distributions; in the early 2000s, Bertsimas and Thiele [33] was the first work to model random variables as uncertain parameters and apply RO to the deterministic problem. In the context of multistage decision making, this leads to *open-loop problems*. A drawback is that these problems had to be reoptimized at each time period, as a necessary trade-off to achieve tractable formulations.

In addition, if the knowledge of the probability distributions driving the random variables is imprecise, but the manager knows that the distribution belongs to a family of distributions, then it is possible to implement an RO approach to the uncertain probability density functions themselves. The manager optimizes his/her objective over the worst-case value of the probabilities. This is referred to in the literature as the *minimax* or *min-max* approach (rather than RO) [39–41]. Thiele [42] applies the RO approach using polyhedral uncertainty sets to stochastic optimization problems and provides theoretical insights into the solution. Unfortunately, the RO approach to SP is only as tractable as the underlying SP problem for the nominal probabilities.

Goh and Sim [43] suggest tractable approximations to distributionally RO using piecewise linear decision rules. Ben-Tal *et al.* [44] propose a framework for RO that extends the standard notion of robustness by allowing the decision maker to vary the protection level across the uncertainty set. This captures the fact that at least some partial probabilistic description of the world is available in many applications such as finance. The approach in their work [44] allows for different performance guarantees for different subsets within $\mathcal{P}$, where $\mathcal{P}$ represents the set of possible underlying probability measures for the random variables. For

instance, performance guarantees of a portfolio can then be linked in a smooth way to the performance of the market as a whole. The authors call this new approach the *soft robust approach* and show that it preserves convexity properties of the nominal problem.

Dimensionality issues explain why researchers have focused on the alternative view of RO, which incorporates uncertainty to the *deterministic* formulation of the problem, instead of considering a stochastic description of uncertainty. While the tractability of the RO approach is appealing, the limitations of open-loop policies have incited researchers to investigate dynamics models in RO in more depth. Of particular interest has been the development and analysis of decision rules with a specific structure, which are described in the following section.

ROBUST DYNAMIC OPTIMIZATION

Linear Decision Rules and Adjustable Optimization

Ben-Tal *et al.* [45] extend the scope of RO by introducing the adjustable RO methodology. Consider the uncertain linear programming problem

$$\left\{ \min_x \left\{ c^T x : Ax \leq b \right\} \right\}_{\zeta \equiv [A, b, c] \in \mathcal{Z}}, \quad (4)$$

where $\zeta \equiv [A, b, c]$ lies in the uncertainty set $\mathcal{Z} \subset \mathbb{R}^n \times \mathbb{R}^{m \times n} \times \mathbb{R}^m$, a nonempty compact convex set. (This section uses the same notation as that is used in Ben-Tal *et al.*'s work [45].)

The RC of the uncertain problem (4) is defined as

$$\min_x \left\{ \sup_{\zeta \equiv [A, b, c] \in \mathcal{Z}} (c^T x) : Ax - b \leq 0 \right. \\ \left. \forall \zeta \equiv [A, b, c] \in \mathcal{Z} \right\}.$$

In the traditional RO approach, all the variables represent “here-and-now” decisions, so that the optimal solution x must be chosen to optimize the worst-case

objective over all possible values of ζ in $\mathcal{Z}$. Ben-Tal *et al.* [45] suggest to incorporate “wait-and-see” decisions; that is, decisions that are taken after the uncertainty is realized. In the RO terminology, the variables that correspond to recourse action are called *adjustable*, while the others are called *nonadjustable*. The vector x in Equation (4) is partitioned according to nonadjustable (u) and adjustable (v) variables such that $x = (u^T, v^T)^T$ and Problem (4) becomes

$$\min_{(s, u), v} \left\{ s : c^T \begin{pmatrix} u \\ v \end{pmatrix} \leq s, Uu + Vv \leq b \right\}_{[U, V, b, c] \in \mathcal{Z}},$$

where (s, u) represents the nonadjustable part of the solution. The uncertain LP problem (4) can be rewritten w.l.o.g. (after redefining parameters appropriately) as

$$LP_{\mathcal{Z}} = \left\{ \min_{u, v} c^T u : Uu + Vv \leq b \right\}_{[U, V, b] \in \mathcal{Z}}. \quad (5)$$

The matrix V is called the *recourse matrix*. When V is not subject to uncertainty, Problem (5) is a *fixed-recourse* LP.

Definition 1. The adjustable robust counterpart (ARC) of the uncertain LP problem $LP_{\mathcal{Z}}$ is defined as

$$ARC : \min_u \left\{ c^T u : \forall \zeta = [U, V, b] \in \mathcal{Z} \exists v : \right. \\ \left. Uu + Vv \leq b \right\}. \quad (6)$$

ARC has a larger robust feasible set and hence is more flexible and less conservative than RC. On the other hand, it is a semi-infinite LP problem; it suffers from computational tractability issues and is NP-hard even for simple uncertainty sets. As a remedy, the authors introduce the affinely adjustable robust counterpart (AARC) of an uncertain LP by restricting the adjustable variables to be *affine* functions of the corresponding data. In other words, v is forced to be of the form

$$v = w + W\zeta$$

for some w, W parameters to be determined.

Definition 2. AARC of Equation (5) is defined as the optimization problem:

$$\min_{u,w,W} \left\{ c^T u : Uu + V(w + W\zeta) \leq b \right. \\ \left. \forall \zeta = [U, V, b] \in \mathcal{Z} \right\}. \quad (7)$$

Ben-Tal *et al.* [45] show that if the uncertainty set $\mathcal{Z}$ in a *fixed-recourse* problem $LP_{\mathcal{Z}}$ is computationally tractable (in the sense that a tractable separation oracle exists), then the AARC is also computationally tractable, that is, polynomially solvable. When the uncertainty set is also “well structured” (i.e., given by a list of linear matrix inequalities such as polyhedral, conic-quadratic, or semidefinite representations), then the corresponding AARC is also “well structured” and thus can be solved by linear or semidefinite programming techniques. On the other hand, if the recourse matrix V is subject to uncertainty, the AARC of $LP_{\mathcal{Z}}$ can become computationally intractable. The authors [45] show that in many such cases, AARC has a tight computationally tractable approximation (which is an explicit semidefinite programming problem). Ben-Tal *et al.* [46] apply the AARC heuristic to the two-echelon multiperiod supply chain problem (specifically, a retailer–supplier flexible commitment (RSFC) problem) and derive a single deterministic convex optimization problem that is either a linear or a conic-quadratic problem.

Ordóñez and Zhao [47] identify the conditions on the uncertainty set that would lead to a tractable ARC approach in the case of a robust capacity expansion problem (RCEP) for network flows. They consider the classic network flow problem with additional decision variables representing arc capacity expansions. The capacity expansion problem can be written as

$$z_D(b, c) = \min_{x,y} c^T x \\ \text{s.t. } Nx = b \\ x \leq u + y \\ d^T y \leq q \\ x, y \geq 0, \quad (8)$$

where $c \in \mathbb{R}^m$ are the transportation cost coefficients, $x \in \mathbb{R}^m$ are the arc flow variables, and $y \in \mathbb{R}^m$ are the decision variables representing the new arc capacities. $N \in \mathbb{R}^{n \times m}$ is the node-arc incidence matrix, initial arc capacities are given by $u \in \mathbb{R}^m$ and the demand–supply vector is given by $b \in \mathbb{R}^n$. Expanding the capacity of arc i costs d_i where q is the total budget for investment. The demand b and the travel times c belong to closed, convex and bounded uncertainty sets U_b and U_c , respectively. It is assumed that the y variables are determined prior to the realization of the uncertain data (b, c) and the flow variables x will adapt to the realized data. Then, the ARC of RCEP is defined as

$$z_{\text{ARC}} = \min_{y, \gamma} \gamma \\ \text{s.t. } d^T y \leq q \\ y \geq 0 \\ \forall c \in U_c, b \in U_b \exists x: \begin{cases} Nx = b \\ 0 \leq x \leq u + y \\ c^T x \leq \gamma. \end{cases}$$

Ordóñez and Zhao [47] present three cases (problem with fixed demand, single commodity problem with uncertain demand, and multicommodity problem with uncertain demand), where the RCEP is formulated as a conic problem and solved by interior point methods in polynomial time.

Shapiro and Nemirovski [12] state that the main reason for using linear decision rules is their tractability, but linear decision rules are rarely optimal. In other words, there is no guarantee that the true optimal solution is close to the one given by the linear decision rule and the optimality gap is not known. Linear decision rules may perform poorly or even lead to infeasible instances even in the case of complete recourse. Chen *et al.* [48] give the following example: suppose that the support of $\tilde{z}$ is $\mathcal{W} = \{-\infty, \infty\}$. Then, the nonnegativity constraint on

$$w(\tilde{z}) = w^0 + \sum_{k=1}^N w^k \tilde{z}_k$$

implies that

$$w^k = 0 \quad \forall k \in \{1, \dots, N\},$$

and the decision rule reduces to $w(\tilde{z}) = w^0$, which is independent of the underlying uncertainty and may lead to infeasibility.

Ben-Tal *et al.* [49] extend the AARC approach by relaxing the “uncertain-but-bounded” assumption of RO that characterizes the uncertain parameters. Requiring that all realizations of the uncertain data lie in the uncertainty set may be pessimistic (leading to overly large sets) or infeasible if the random variables have unbounded support. The approach in Ben-Tal *et al.* [49] exhibits controlled performance degradation for “large deviations” in the uncertain data. Assume that the uncertainty set $\mathcal{Z}$ represents the typical range for the uncertain data. When $\zeta \in \mathcal{Z}$, the solution must satisfy the constraints of the problem. When the data ζ falls outside the uncertainty set $\mathcal{Z}$, the violation of the constraints should not exceed a prescribed multiple of the deviation of the data from its normal range. These multiples serve as “global sensitivities” of the constraints. Ben-Tal *et al.* [49] call this extension of AARC the *comprehensive RC* of uncertain linear problems.

Piecewise Constant Rules and Adaptive Optimization

Bertsimas and Caramanis [50] introduce a variable degree of adaptability on the grounds that complete adaptability can be too expensive and assuming the exact realization of uncertainty (which is required to implement AARC above) is overly optimistic. The generic problem the authors consider is

$$\min \left\{ c^T x : Ax \geq b, \forall A \in \mathcal{P} \right\}, \quad (9)$$

where $\mathcal{P}$ is a polytope. The reoptimization formulation is given by

$$\max_{A \in \mathcal{P}} \left\{ \min \left\{ c^T x : Ax \geq b \right\} \right\}. \quad (10)$$

The authors introduce the concept of k -adaptability (Problem (11)), which is formulated as a disjunctive optimization problem with infinitely many constraints. The decision maker selects k solutions and commits to one solution after uncertainty is revealed; at least one of the k solutions must

be feasible regardless of the realization of the uncertainty.

$$\begin{aligned} \min \quad & \max \{ c^T x_1, c^T x_2, \dots, c^T x_k \} \\ \text{s.t.} \quad & [Ax_1 \geq b \text{ or } Ax_2 \geq b \text{ or } \dots \text{ or } Ax_k \geq b] \\ & \forall A \in \mathcal{P}. \end{aligned} \quad (11)$$

Problem (11) is equivalent to the k -partitioning problem (12) where the uncertainty set $\mathcal{P}$ has been partitioned into a finite number k of regions: $\mathcal{P} = \mathcal{P}_1 \cup \mathcal{P}_2 \cup \dots \cup \mathcal{P}_k$. The decision maker learns which region of the partition will contain the realization of the uncertainty before he has to commit to a solution.

$$\min_{\mathcal{P} = \mathcal{P}_1 \cup \dots \cup \mathcal{P}_k} \left[\begin{array}{l} \min \max \{ c^T x_1, c^T x_2, \dots, c^T x_k \} \\ \text{s.t.} \quad Ax_1 \geq b, \forall A \in \mathcal{P}_1 \\ \quad \quad \quad \vdots \\ \quad \quad \quad Ax_k \geq b, \forall A \in \mathcal{P}_k \end{array} \right]. \quad (12)$$

Problem (12) represents an application of finite adaptability to *single-stage optimization*. For two-stage optimization as in the ARC model (6), the problem becomes

$$\min_{\mathcal{P} = \mathcal{P}_1 \cup \dots \cup \mathcal{P}_k} \left[\begin{array}{l} \min : c^T u \\ \text{s.t.} \quad Uu + Bv_1 \geq b, \forall (U, V) \in \mathcal{P}_1 \\ \quad \quad \quad \vdots \\ \quad \quad \quad Uu + Bv_k \geq b, \forall (U, V) \in \mathcal{P}_k \end{array} \right]. \quad (13)$$

Let V_{RO} , V_{ReOpt} , V_{adapt}^k be the optimal objective values of Problems 9, 10, and (12), respectively. We have

$$V_{\text{RO}} \geq V_{\text{adapt}}^k \geq V_{\text{ReOpt}}.$$

Furthermore, with an additional continuity assumption, $\lim_{k \rightarrow \infty} V_{\text{adapt}}^k = V_{\text{ReOpt}}$. Hence, finite adaptability bridges the gap between RO (total lack of adjustability, where all decision variables are here-and-now) and reoptimization (total adjustability, where all decision variables are wait-and-see).

While the k -adaptability problem was formulated above as a disjunctive program,

it can also be formulated as a bilinear optimization program. For $k = 2$, the bilinear optimization problem becomes

$$\begin{aligned} \min \quad & \max\{c^T x_1, c^T x_2\} \\ \text{s.t.} \quad & u_{i,j}[(A^l x_1)_i - b_i] + (1 - u_{i,j})[(A^l x_2)_j - b_j] \geq 0 \\ & \forall 1 \leq i, j \leq m \quad \forall 1 \leq l \leq K \\ & 0 \leq u_{i,j} \leq 1, \quad \forall 1 \leq i, j \leq m. \end{aligned}$$

m is the number of rows of the constraint matrix A and K is the number of extreme points of the uncertainty set $\mathcal{P}$, where $\mathcal{P}$ is defined as the convex hull of its extreme points: $\mathcal{P} = \text{conv}(A^1, \dots, A^K)$. Bertsimas and Caramanis [50] prove that obtaining the optimal partition $\mathcal{P} = \mathcal{P}_1 \cup \mathcal{P}_2$ in 2-adaptability is NP-hard in general, provide a hierarchy of the levels of adaptability, and propose a heuristic tractable algorithm.

Bertsimas and Goyal [51,52] consider two-stage adaptive optimization problems and investigate the power and limitations of robust solutions and affine policies. In their work [51], it is shown that the RO approach is a good approximation to solving the corresponding two-stage mixed integer stochastic optimization problem to optimality. They compare the optimal cost of the robust problem to the optimal costs of the stochastic problem and the adaptability problem. If the uncertainty set and the probability distribution over the uncertain set are symmetric, and if the second-stage variables are continuous variables, the optimal cost of the robust problem is at most twice the expected cost of the optimal two-stage solution to the stochastic problem. In another work [52], Bertsimas and Goyal show that an affine policy is optimal if the uncertainty set $u \in \mathbb{R}_+^m$ is a convex combination of $m + 1$ affinely independent points in $\mathbb{R}_+^m$ and this optimality result is almost tight. They also prove that if the uncertainty set is a polytope, the worst-case cost occurs at an extreme point of the uncertainty set. On the other hand, for uncertainty sets with $m + 2$ nonzero extreme points, the affine policy is suboptimal. The authors also give a lower and upper bound for the performance of an optimal affine policy compared to an optimal fully adaptable two-stage solution [52].

Other Approaches

Thiele *et al.* [53] develop an RO approach for generic two-stage stochastic problems with uncertainty on the right-hand side. The authors apply a cutting-plane algorithm based on Kelley's algorithm to the robust linear problem with general recourse and test the methodology on a multi-item newsvendor problem and production planning example where the demand is uncertain but must be met.

Chen *et al.* [54] generalize the robust linear optimization frameworks of Ben-Tal and Nemirovski [23] and Bertsimas and Sim [28] by introducing a new uncertainty set that captures the asymmetry of the underlying random variables through the use of new deviation measures (forward and backward deviations). They integrate these deviation measures to the uncertainty set and obtain solutions to chance-constrained problems. Applying the linear decision rule of Ben-Tal *et al.* [45], Chen *et al.* [54] present a tractable RO approach in order to find less conservative feasible solutions for SP with chance constraints. This framework also leads to the computational scalability of multistage stochastic models. Chen *et al.* [48] propose a novel framework to approximate multistage stochastic optimization by introducing two new piecewise linear decision rules. The first one is called *deflected linear decision rule*, which is best suited for SP problems with semicomplete recourse and provides a tighter approximation of the original objective function than the linear decision rule. The second one is called *segregated linear decision rule*, which is best suited for SP problems with general recourse. When combined with the first rule, the *segregated linear decision rule* exhibits better performance than both linear and deflected linear decision rules. Under these new piecewise linear rules, the authors show that the computational tractability of the problems is preserved. Chen and Zhang [55] and See and Sim [56] extend the theory of RO to approximate solutions of multistage problems. See and Sim [57] apply these RO approaches to multiperiod inventory control.

As a novel application, Düzgün and Thiele [58] apply RO to R&D project management

problems where investments are done in stages (such as the phases of a drug trial) and cash flows are uncertain. They describe how to address the modeling challenges raised in the RO framework by the discrete, stochastic outcome of each phase (success or failure) and the computational challenges raised by the use of binary variables to represent project selection.

CONCLUSIONS

Dynamic models of RO have been the focus of significant research efforts, both in terms of theory and applications. Piecewise constant, linear and piecewise linear decision rules have been thoroughly investigated. The use of RO has allowed for the design of an elegant, intuitive, and tractable framework to sequential decision making under uncertainty.

DYNAMIC PRICING STRATEGIES FOR MULTIPRODUCT REVENUE MANAGEMENT PROBLEMS

COSTIS MAGLARAS
Graduate School of Business,
Columbia University,
New York, New York

INTRODUCTION

We consider a firm that owns a fixed capacity of a certain resource that is consumed in the process of producing or offering multiple products or services, and which must be consumed over a finite time horizon. The firm's problem is to maximize its total expected revenues by dynamically selecting the price of each of its products over time. Revenue management problems of that sort gained interest in the late 1970s in the context of the airline industry, and have since been successfully introduced in a variety of other areas such as hotels, cruise lines, rental cars, and retail. This article considers three variants of the above problem. In the first, the firm offers just one product and is assumed to be a monopolist or to operate in a market with imperfect competition, and thus to have power to influence the demand for each product by varying its price. In this setting, the firm's problem is to choose a dynamic pricing strategy for its product in order to optimize expected revenues. In the second variant, the firm offers many products that consume the capacity of the same scarce resource, and again has pricing power and seeks to optimize its expected revenues by choosing a multidimensional dynamic pricing policy. Finally, in the third variant, prices are assumed to be fixed either by the competition or through a higher-order optimization problem, and the firm's problem is now to choose a dynamic capacity allocation rule that controls when to accept new requests for each of these products. In the sequel, the first two will be referred to as *dynamic pricing*

problems, while the third will be referred to as a *capacity control* problem.

This article illustrates how these three problems can be reduced to a common formulation, thus connecting prior results that have appeared in the literature under a unified framework, and explores some of the consequences of this formulation. Specifically, we show that the multiproduct dynamic pricing and the capacity control problems can be recast within this common framework, and be treated as different instances of a single-product pricing problem for appropriately selected concave revenue functions. Broadly speaking, this is done by decoupling the revenue maximization problems in two parts: first, at each point in time the firm selects an aggregate capacity consumption rate from all products and, second, it computes the vector of demand rates to maximize instantaneous revenues subject to the constraint that all products jointly consume capacity at the aforementioned rate. The latter is akin to the basic microeconomics problem of resource allocation subject to a budget constraint, and gives rise to an appropriate *aggregate revenue rate function* in each case.

Adopting this common formulation, we review some of the key structural results regarding the monotonicity properties of the value function and the associated controls, which were derived in the literature [1–6]. We present the deterministic and continuous (fluid) approximations of the dynamic pricing problems described above, review their solution, the pricing heuristics that can be gleaned from them, and the performance bounds that they offer for the expected revenues of the stochastic and discrete revenue maximization of original interest.

The remainder of this article is structured as follows. This section concludes with a brief literature review. The section titled “Single-Product Dynamic Pricing Problem” formulates the single-product dynamic pricing problem and reviews some known structural results, and subsequently studies the deterministic and continuous (fluid)

analog of the dynamic pricing problem. The section titled “Multiple Products, Single Resource” studies the multiproduct variants described above. The section titled “Dynamic Pricing Network Revenue Management Problems” outlines how the same approach can be extended to a network setting. The section titled “Extensions” offers some concluding remarks, including interesting extensions of the baseline models we study. In terms of style of exposition, we focus on specifying the underlying models and providing sketches and intuition for the type of analysis that one may carry through, and refer the reader to appropriate references for details on lengthy derivations and proofs.

The papers by Elmghraby and Keskinocak [7], Bitran and Caldentey [8], and McGill and van Ryzin [9], and the book by Talluri and van Ryzin [10] provide comprehensive overviews of the areas of dynamic pricing and revenue management. The modeling framework adopted in this paper closely matches that of Gallego and van Ryzin [1,2]. Additional references on the capacity control formulation are Brumelle and McGill [11] and Lautenbacher and Stidhman [4]. The reduction of the multiproduct and capacity control problems to single-product pricing problems and their subsequent solutions are from Maglaras and Meissner [6]. The asymptotic analysis that is briefly reviewed in this article builds on the setup used in Refs 1 and 2 and Cooper [12], and the results reviewed here are adopted from [6]. The idea of efficient controls and that of a notion of an efficient frontier on how to choose the product level pricing and capacity control decisions to achieve a desired capacity absorption rate is from [6]. Related ideas have appeared in slightly different settings in Talluri and van Ryzin [13], in the context of a capacity control problem for a model with customer choice among products, and in Feng and Xiao [14,15], while studying pricing problems with a predetermined set of price points; our presentation of this topic borrows from [6]. The pricing and capacity control heuristics that we discuss have appeared in many references such as Gallego and van Ryzin [1,2], McGill and van Ryzin [9], Feng and Xiao [15], Lin *et al.* [6,16]. The feedback form of the static pricing policy

that is optimal for the deterministic and continuous (fluid) analog of the stochastic and discrete dynamic pricing problem is from [6] and the property of asymptotic optimality of the “resolving” pricing heuristic that is based on that feedback policy is also from [6].

SINGLE-PRODUCT DYNAMIC PRICING PROBLEM

Model

Consider a firm endowed with C units of capacity of a product that is to be sold over a finite horizon τ , and where capacity cannot be replenished up to that time. The salvage value of the remaining capacity at time τ is assumed to be 0. (A constant per-unit salvage value would also result in formulations similar to those developed below.) The firm is either a monopolist or is assumed to operate in a market with imperfect competition, and, in that, has power to influence the demand for each product by varying its menu of prices. Let $p(t)$ denote the price posted at time t . The demand process is assumed to be a nonhomogeneous Poisson process with rate vector λ determined through a demand function $\lambda(p(t))$, where $\lambda : \mathcal{P} \rightarrow \mathcal{L}$, $\mathcal{P} \subseteq \mathbb{R}$ is the set of feasible price vectors, and $\mathcal{L} = \{x \geq 0 : x = \lambda(p), p \in \mathcal{P}\} \subseteq \mathbb{R}_+$ is the set of achievable demand rate vectors. We assume that $\mathcal{L}$ is a convex set. For ease of exposition, the demand function $\lambda(\cdot)$ is assumed to be stationary; an extension to allow for non-stationarities could follow Gallego and van Ryzin [1,2], and Zhao and Zheng [5]. We consider *regular* demand functions that satisfy some additional conditions. In the sequel, x' denotes the transpose of any matrix x , for any real number y , $y^+ := \max(0, y)$, e is the vector of 1's of appropriate dimension and “a.s.” stands for almost surely.

Definition 1. A demand function is said to be regular if it is a continuously differentiable, bounded function, and: (a) $\lambda(p)$ is strictly decreasing in p , (b) $\lim_{p \rightarrow \infty} \lambda(p) = 0$, and (c) the revenue rate $p\lambda(p)$ is bounded for all $p \in \mathcal{P}$ and has a finite maximizer $\bar{p}$.

We assume that there exists a continuous inverse demand function $p(\lambda)$, $p : \mathcal{L} \rightarrow \mathcal{P}$,

which maps an achievable demand rate λ to the corresponding price $p(\lambda)$. This allows us to view the demand rate as the firm's control, and infer the appropriate price using the inverse demand function. The expected revenue rate can be expressed as a function of the vector of demand rates λ as $R(\lambda) := \lambda p(\lambda)$, and is assumed to be continuous, bounded, and strictly concave.

Example 1 [Linear Demand Model].

The demand for the product at price p is given by $\lambda(p) = \Lambda - bp$, where $\Lambda > 0$ is the market potential for the product and $b > 0$ is the price sensitivity parameter. The inverse demand and revenue functions are $p(\lambda) = (\Lambda - \lambda)/b$ and $R(\lambda) = \lambda(\Lambda - \lambda)/b$, respectively.

Example 2 [Logit Demand Model].

$\lambda(p) = \Lambda e^{-bp}/(1 + e^{-bp})$, $p(\lambda) = (1/b)\ln(\Lambda/\lambda - 1)$, and $R(\lambda) = (\lambda/b)\ln(\Lambda/\lambda - 1)$, respectively.

The problem that we address is roughly described as follows: given an initial capacity C , a selling horizon τ , and a demand function that maps a posted price to a corresponding instantaneous demand rate, the firm's goal is to choose a nonanticipating dynamic pricing strategy in order to maximize its total expected revenues.

We adopt a discrete-time formulation, that is, one where time has been discretized in small intervals of length δt , indexed by $t = 1, \dots, T$, such that $\mathbb{P}(\text{one product request in } [0, \delta t]) = \lambda \delta t + o(\delta t)$, $\mathbb{P}(\text{two product requests in } [0, \delta t]) = \lambda^2 (\delta t)^2 + o((\delta t)^2)$, and so on, where $o(x)$ implies that $o(x)/x \rightarrow 0$ as $x \rightarrow 0$. In addition, $T = \tau/\delta t$. With slight abuse of notation, we write λ in place of $\lambda \delta t$, and refer to λ either as the demand or as the buying probability. The random demand in period t , denoted by $\xi(t; \lambda)$, is Bernoulli with probability $\lambda(t) = \lambda(p(t))$, and $\mathbb{P}(\xi(t) = 1) = \lambda(p(t))$ and $\mathbb{P}(\xi(t) = 0) = 1 - \lambda(p(t))$. Treating the demand rate λ as the control variables (prices are inferred via the inverse demand relationship), the discrete-time formulation of the dynamic pricing problem of Gallego

and van Ryzin [1] is

$$\max_{\{\lambda(t), t=1, \dots, T\}} \left\{ \mathbb{E} \left[\sum_{t=1}^T p(\lambda(t)) \xi(t; \lambda) \right] : \sum_{t=1}^T \xi(t; \lambda) \leq C \text{ a.s. and } \lambda(t) \in \mathcal{L} \forall t \right\}. \quad (1)$$

Analysis of the Dynamic Program

Let x denote the number of remaining units of capacity at the beginning of period t , and $V(x, t)$ be the expected revenue-to-go starting at time t with x units of capacity left. Then, the Bellman equation associated with Equation (1) is

$$V(x, t) = \max_{\lambda \in \mathcal{L}} \left\{ \lambda [p(\lambda) + V(x-1, t+1)] + (1-\lambda) V(x, t+1) \right\}, \quad (2)$$

with the boundary conditions

$$V(x, T+1) = 0 \forall x \quad \text{and} \quad V(0, t) = 0 \forall t. \quad (3)$$

Letting $\Delta V(x, t) = V(x, t+1) - V(x-1, t+1)$ denote the marginal value of one unit of capacity as a function of the state (x, t) , Equation (2) can be rewritten as

$$V(x, t) = \max_{\lambda \in \mathcal{L}} \{ R(\lambda) - \lambda \Delta V(x, t) \} + V(x, t+1). \quad (4)$$

The optimal control $\lambda^*(x, t)$ is computed as follows:

$$\lambda^*(x, t) = \arg \max_{\lambda \in \mathcal{L}} \{ R(\lambda) - \lambda \Delta V(x, t) \},$$

where $R(\cdot)$ is a concave increasing revenue function. Using the properties of $R(\cdot)$, one can show that $\lambda^*(x, t)$ is decreasing in $\Delta V(x, t)$, which, using a backwards induction argument in t , gives that $\Delta V(x, t)$ is decreasing in x and t . These monotonicity results are the key structural properties that one can extract from the dynamic program that is summarized below; a proof can be found in [10] (Proposition 5.2, Chapter 4).

Proposition 1 [10, Proposition 5.2 Chapter 4]. *For the problem defined in Equation (1):*

1. $\lambda^*(x, t)$ is decreasing in the marginal value of capacity $\Delta V(x, t)$, and
2. $\Delta V(x, t)$ is decreasing in x and t .

The dynamic program in Equations (2) and (3) admits a closed-form solution for the special case of the exponential demand model, and is fairly easy to solve numerically in other cases. The optimal policy takes the form of a two-dimensional table that specifies a price for each (remaining inventory, time) pair. The optimal price path continuously decreases price between sales, and jumps up at every sales epoch.

The Fluid Model

The “fluid” model has deterministic and continuous dynamics, and in broad terms is obtained by replacing the Poisson demand process with nonhomogeneous rate $\lambda(t)$, where demand requests arrive stochastically over time and require discrete units of capacity, by a deterministic and continuous process where demand for the product arrives continuously at the deterministic rate $\lambda(t)$. The resulting inventory dynamics (in discrete-time) are given by

$$X(t+1) = X(t) - \lambda(t), \quad x(0) = C, \quad X(T) \geq 0.$$

This deterministic analog is a simplification of the discrete and stochastic model we started with in the previous sections. It can be rigorously justified as a limit under a law-large-numbers type of scaling as the potential demand and the capacity grow proportionally large, and, as such, one would expect to provide more useful analysis and policy recommendations in settings where the firm has many units to sell and operates in a market with high demand. For example, one would expect that the discrete and stochastic nature of the pricing problem to be relevant when selling four newly constructed single family homes over the course of 24 weeks, but it may be less relevant when selling 4000

pairs of skis over a similar time duration from, say, October to March.

The fluid model formulation of the dynamic pricing problem is one where the firm selects a demand rate $\lambda(t)$ (or a price) at each time t to

$$\max_{\{\lambda(t), t=1, \dots, T\}} \left\{ \sum_{t=1}^T R(\lambda(t)) dt : \sum_{t=1}^T \lambda(t) dt \leq C \text{ and } \lambda(t) \in \mathcal{L} \forall t \right\}. \quad (5)$$

Optimal Policy for Fluid Pricing Problem.

An important result derived in Gallego and van Ryzin [1] is that a constant price (and thus a constant demand rate) is optimal for Equation (5). Specifically, let $\hat{\lambda} = \operatorname{argmax}\{R(\lambda) : \lambda \in \mathcal{L}\}$ and $\hat{p} = p(\hat{\lambda})$ be the demand rate and price that maximize the revenue rate disregarding any capacity considerations, respectively. Also, let $\lambda^0 = C/T$ be the *run-out* rate that depletes capacity at time T , and $p^0 = p(\lambda^0)$.

Proposition 2 [10, Section 5.2.1.2]. *The optimal solution for Equation (5) denoted by $\bar{\lambda}$ and $\bar{p}$ is given by*

$$\bar{\lambda}(x, t) = \min(\lambda^0, \hat{\lambda}) \quad \text{and} \quad \bar{p} = \max(p^0, \hat{p}) \quad \text{for } t = 1, \dots, T. \quad (6)$$

Intuitively, the firm uses the revenue maximizing price $\hat{p}$ unless this would deplete the capacity too soon, in which case it increases its unit price to p^0 and sell its capacity by time T , while accruing higher total revenues. The proof is simple and exploits the structure of Equation (5) that seeks to maximize a concave function over the capacity constraint; the first-order optimality conditions set the marginal revenue rates at each time t to be equal, which, in turn, is achieved via a static pricing policy.

The static nature of the optimal policy for the fluid control problem is simple and intuitive, but also lacks the capability of corrective action against stochastic fluctuations. This does not arise in the fluid formulation, where the capacity is drained along the optimal deterministic trajectory, but it

is relevant for the stochastic problems of original interest. Alternatively, $\bar{\lambda}$ can also be expressed in the feedback form. Note that the deterministic trajectory of the fluid model is such that $x/(T-t) = C/T$ for all t if $\hat{\lambda} \geq C/T$, and $x/(T-t) = (C - \hat{\lambda}t)/(T-t) \geq C/T$ if $\hat{\lambda} < C/T$. Given this observation, $\bar{\lambda}$ can be expressed as

$$\bar{\lambda}(x, t) = \min\left(\hat{\lambda}, \frac{x}{T-t}\right). \quad (7)$$

An Upper Bound on Achievable Performance. Apart from good policy recommendations, the fluid model offers a useful upper bound on the achievable expected revenue in the underlying stochastic and discrete problem in Equation (1). Specifically, Gallego and van Ryzin [1] showed the following:

Proposition 3 [10, Section 5.2.2.3]. $V(C, 1) \leq (\bar{\lambda}\bar{p})T$.

This result establishes a tractable limit for the best achievable performance that is useful in establishing suboptimality gaps for heuristics that one may wish to use, and to prove asymptotic optimality results of candidate policies that achieve that bound in an appropriate asymptotic sense. As an illustration, we conclude this section with a brief sketch of the setup and nature of such an asymptotic optimality result.

Using k as an index, we consider a sequence of problems with demand model $\lambda^k(\cdot) = k\lambda(\cdot)$ and capacity $C^k = kC$, and let k increase to infinity; hereafter, a superscript k will denote quantities that scale with k . Let N denote a unit rate Poisson process, and recall that the functional strong-law-of-large numbers for the Poisson process asserts that as $k \rightarrow \infty$ and for all $t \geq 0$,

$$\frac{N(kt)}{k} \rightarrow t \quad \text{a.s.} \quad (8)$$

The remaining capacity at time t is denoted by $X^k(t)$ and is given by

$$X^k(t) = C^k - N(A^k(t)), \quad (9)$$

where $N(A^k(t))$ is the cumulative number of sales up to period t and $A^k(t) = \sum_{s=1}^t \lambda^k(s) ds$. Let R^k denote the total cumulative revenue extracted under policy (Eq. 6). The firm uses the constant price vector $\bar{p}$, which induces the demand rates $\lambda^k(\bar{p}) = k\bar{\lambda}$. Under this policy, $A^k(t) = \bar{\lambda}kt$, and the capacity dynamics are $X^k(t) = (C^k - N(A^k(t)))^+$. (The subscript is used to identify the policy.) As $k \rightarrow \infty$

$$\frac{N(A^k(t))}{k} \rightarrow \bar{\lambda}t \quad \text{a.s., } \forall t = 1, \dots, T, \quad (10)$$

from which it follows that as $k \rightarrow \infty$ and for all $t \in [0, T]$ $X^k(t)/k \rightarrow C - \bar{\lambda}t$ a.s. uniformly on compact sets as $k \rightarrow \infty$. Let $\tau^k := \inf\{s \geq 0 : N(\bar{\lambda}ks) \geq C^k\}$ be the random time where the capacity is depleted. Then, $R^k := \bar{p}N(k\bar{\lambda} \min(T, \tau^k)) - \delta$, where δ is a random variable that corrects revenues for the case where $\tau^k < T$; clearly $\delta < \bar{p}$. (We do not delve into an accurate description of δ , since it is asymptotically negligible.) Using Equation (10) and arguing by contradiction, one can easily conclude that $(T - \tau^k)^+ \rightarrow 0$ a.s., as $k \rightarrow \infty$, and get the following:

Proposition 4 [6, Proposition 4]. *Suppose that demand and capacity are scaled according to $\lambda^k(\cdot) = k\lambda(\cdot)$ and $C^k = kC$, and consider the static pricing policy $p^k(x, t) = \bar{p}$ for all x, t and all k . Then, as $k \rightarrow \infty$, $X^k(t)/k \rightarrow C - \bar{p}t$ a.s., uniformly in t , and $\frac{1}{k}R^k \rightarrow \bar{p}\bar{\lambda}T$ a.s.*

Given Proposition 3, we have that $R^k \leq k\bar{p}\bar{\lambda}T$. Applying the bounded convergence theorem gives that $\mathbb{E}R^k/k \rightarrow \sum_{i=1}^n \bar{p}_i \bar{\lambda}_i T$, and establishes the asymptotic optimality of the static pricing heuristic in Equation (6). A similar proof can establish the asymptotic optimality of the feedback rule given in Equation (7), which when applied to the stochastic system of interest yields a dynamic pricing policy; see Maglaras and Meissner [6].

MULTIPLE PRODUCTS, SINGLE RESOURCE

This section studies the multiproduct dynamic pricing and capacity control problems studied by Gallego and van Ryzin [2] and Lee and Hersh [3], respectively, among others.

Problem Formulations

Dynamic Pricing Problem. The basic elements of the problem are similar to those in the section titled “Single Product Dynamic Pricing Problem” with the key difference that the firm is now selling multiple products or services, indexed by $i = 1, \dots, n$ that consume the capacity C . Each product i request requires one unit of capacity. Let $p(t) = [p_1(t), \dots, p_n(t)]$ denote the vector of prices at time t . The demand process is assumed to be an n -dimensional nonhomogeneous Poisson process with rate vector λ determined through a demand function $\lambda(p(t))$, where $\lambda : \mathcal{P} \rightarrow \mathcal{L}$, $\mathcal{P} \subseteq \mathbb{R}^n$ is the set of feasible price vectors, and $\mathcal{L} = \{x \geq 0 : x = \lambda(p), p \in \mathcal{P}\} \subseteq \mathbb{R}_+^n$ is the set of achievable demand rate vectors. We assume that $\mathcal{L}$ is a convex set. As in the section titled “Single Product Dynamic Pricing Problem,” the demand function $\lambda(\cdot)$ is assumed to be stationary. The definition of regular demand functions is as follows:

Definition 2. A demand function is said to be regular if it is a continuously differentiable, bounded function, and, (a) for each product i , $\lambda_i(p)$ is strictly decreasing in p_i , (b) $\lim_{p_i \rightarrow \infty} \lambda_i(p) = 0$ (i.e., consumers have bounded wealth), and (c) the revenue rate $p' \lambda(p) = \sum_{i=1}^n p_i \lambda_i(p)$ is bounded for all $p \in \mathcal{P}$ and has a finite maximizer $\bar{p}$.

We assume that there exists a continuous inverse demand function $p(\lambda), p : \mathcal{L} \rightarrow \mathcal{P}$, that maps an achievable vector of demand rates λ into a corresponding vector of prices $p(\lambda)$. This allows us to view the demand rate vector as the firm’s control, and infer the appropriate prices using the inverse demand function. The expected revenue rate can be expressed as a function of the vector of demand rates λ as $R(\lambda) := \lambda' p(\lambda)$, and is assumed to be continuous, bounded, and strictly concave.

Example 3 [Linear Demand Model]. The demand for product i is given by

$$\lambda_i(p) = \Lambda_i - b_{ii}p_i - \sum_{j \neq i} b_{ij}p_j$$

or (in vector form) $\lambda(p) = \Lambda - Bp$,

where Λ_i is the market potential for product i and b_{ii}, b_{ij} are the price and cross-price sensitivity parameters. The inverse demand and revenue functions are $p(\lambda) = B^{-1}(\Lambda - \lambda)$ and $R(\lambda) = \lambda' B^{-1}(\Lambda - \lambda)$, respectively. Assumption 1 requires that $b_{ii} > 0$ for all i . To ensure that the inverse demand function is well defined and the revenue function is concave, we require that either $b_{ii} > \sum_{j \neq i} |b_{ji}|$ or $b_{ii} > \sum_{j \neq i} |b_{ij}|$ for all i ; both conditions guarantee that B is invertible and that its eigenvalues have positive real parts [17, Theorem 6.1.10].

Example 4 [Multinomial Logit (MNL) Model]. Potential customers arrive with rate Λ and have utilities for each product i given by $v_i - p_i + \xi_i$, where v_i is the deterministic portion that is common to all customers, p_i is the price, and ξ_i is the random term (that differentiates customers) that is drawn from a Gumbel distribution with mean 0 and parameter 1 (the latter is assumed w.l.o.g.), and is IID across products and customers. The no-purchase option has utility $u_0 + \xi_0$, ξ_0 is IID with the ξ_i ’s and $u_0 = 0$. The demand rates for product i is given by

$$\lambda_i(p) = \Lambda \frac{e^{v_i - p_i}}{1 + \sum_j e^{v_j - p_j}}.$$

Again adopting a discrete-time formulation, the random demand vector in each period t , denoted by $\xi(t; \lambda)$, is Bernoulli with probabilities $\lambda(t) = \lambda(p(t))$, and $\mathbb{P}(\xi_i(t) = 1) = \lambda_i(p(t))$ and $\mathbb{P}(\xi_i(t) = 0) = 1 - \lambda_i(p(t))$ for all i . Treating the demand rates λ_i as the control variables (prices are inferred via the inverse demand relationship), the discrete-time formulation of the dynamic pricing problem of Gallego and van Ryzin [2] is

$$\begin{aligned} \max_{\{\lambda(t), t=1, \dots, T\}} & \left\{ \mathbb{E} \left[\sum_{t=1}^T p(\lambda(t))' \xi(t; \lambda) \right] \right. \\ & \left. : \sum_{t=1}^T e' \xi(t; \lambda) \leq C \text{ a.s. and } \lambda(t) \in \mathcal{L} \forall t \right\}. \end{aligned} \quad (11)$$

Capacity Control Problem. The next variant we consider is the one studied by Lee and Hersh [3], where the price vector p and the demand rate vector $\lambda = \lambda(p)$ are fixed, and the firm optimizes over capacity allocation decisions. For this problem and without any loss of generality, we assume that products are labeled such that $p_1 \geq p_2 \geq \dots \geq p_n$. The firm has discretion as to which product requests to accept at any given time. This is modeled through the control $u_i(t)$ that is equal to the probability of accepting a product i request at time t . It is customary to assume that the firm is “opening” or “closing” products, thus considering controls $u_i(\cdot)$ that are 0 or 1, but this need not be imposed as a restriction. The dynamic capacity control problem is the following:

$$\max_{\{u(t), t=1, \dots, T\}} \left\{ \mathbb{E} \left[\sum_{t=1}^T p' \xi(t; u\lambda) \right] : \sum_{t=1}^T e' \xi(t; u\lambda) \leq C \text{ a.s. } 1 \text{ and } u_i(t) \in [0, 1] \forall t \right\}, \quad (12)$$

where $u\lambda$ above denotes the vector with coordinates $u_i \lambda_i$.

The remainder of this section describes how to reduce Equations (11) and (12) into dynamic optimization problems where the control is the (one-dimensional) aggregate capacity consumption rate. The reduced problems can be studied through a unified analysis.

A Common Formulation in Terms of the Aggregate Capacity Consumption

Dynamic Pricing Problem. Let x denote the number of remaining units of capacity at the beginning of period t , and $V(x, t)$ be the expected revenue-to-go starting at time t with x units of capacity left. Then, the Bellman equation associated with Equation (1) is

$$V(x, t) = \max_{\lambda \in \mathcal{L}} \left\{ \sum_{i=1}^n \lambda_i [p_i(\lambda) + V(x-1, t+1)] + (1 - e'\lambda) V(x, t+1) \right\}, \quad (13)$$

with the boundary conditions

$$V(x, T+1) = 0 \quad \forall x \quad \text{and} \quad V(0, t) = 0 \quad \forall t. \quad (14)$$

Letting $\Delta V(x, t) = V(x, t+1) - V(x-1, t+1)$ denote the marginal value of one unit of capacity as a function of the state (x, t) , Equation (13) can be rewritten as

$$\begin{aligned} V(x, t) &= \max_{\lambda \in \mathcal{L}} \left\{ R(\lambda) - \sum_{i=1}^n \lambda_i \Delta V(x, t) \right\} + V(x, t+1) \\ &= \max_{\rho \in \mathcal{R}} \{ R^r(\rho) - \rho \Delta V(x, t) \} + V(x, t+1), \end{aligned} \quad (15)$$

where $\rho := \sum_{i=1}^n \lambda_i$ is the *aggregate* rate of capacity consumption, $\mathcal{R} := \{ \rho : \sum_{i=1}^n \lambda_i = \rho, \lambda \in \mathcal{L} \}$ is the set of achievable capacity consumption rates, and

$$R^r(\rho) := \max_{\lambda} \left\{ R(\lambda) : \sum_{i=1}^n \lambda_i = \rho, \lambda \in \mathcal{L} \right\} \quad (16)$$

is the maximum achievable revenue rate subject to the constraint that all products jointly consume capacity at a rate ρ . Note that Equation (16) is a concave maximization problem over a convex set, and its solution is readily computable, often in closed form. The aggregate revenue function $R^r(\cdot)$ is concave and satisfies the conditions of Assumption 1. The optimal vector of demand rates, denoted by $\lambda^r(\rho)$, is unique and continuous in ρ .

Example 5 [Linear Demand Model]. For $\lambda(p) = \Lambda - Bp$, the associated aggregate revenue function $R(\rho)$ defined through Equation (16) can be expressed as

$$R^r(\rho) = -\alpha_i \rho^2 + \beta_i \rho + \gamma_i \quad \text{for } \rho \in [r_{i-1}, r_i),$$

for $0 = r_0 \leq r_1 \leq r_2 \leq \dots \leq r_I$, and constants $(\alpha_i, \beta_i, \gamma_i)$ and r_i that depend on the model parameters Λ, B, μ , and are such

that $R^r(\rho)$ is continuous, almost everywhere differentiable, and increasing for all $\rho \leq \hat{\rho} := \arg \max_{\rho} R^r(\rho)$. The value of r_{i-1} is that of the smallest capacity consumption rate above which it is optimal to start offering the i most profitable products. The derivation of the constants $(\alpha, \beta, \gamma, r)$ can be found in the Appendix of [18].

Example 6. For the MNL model, straightforward manipulations show that

$$\begin{aligned} R(\rho) &= \rho \ln \left(\sum_j e^{v_j} \right) - \rho \ln(\rho/(\Lambda - \rho)), \\ \lambda_i(\rho) &= \rho \frac{e^{v_i}}{\sum_j e^{v_j}} \quad \text{and} \\ p_i(\rho) &= \ln \left(\sum_j e^{v_j} \right) - \ln(\rho/(\Lambda - \rho)). \end{aligned}$$

Proposition 5. *The dynamic pricing problem (Eq. 11) can be reduced to the dynamic programs (15) and (14) expressed in terms of the aggregate consumption rate. In particular, if $\rho^*(x, t)$ denotes the associated optimal control and $\lambda^*(x, t)$ and $p^*(x, t)$ denote the optimal demand rate and price vectors associated with Equation (11), then, $\lambda^*(x, t) = \lambda^r(\rho^*(x, t))$ and $p^*(x, t) = p(\lambda^r(\rho^*(x, t)))$.*

The Capacity Control Problem. Similarly, the Bellman equation associated with Equation (12) is

$$\begin{aligned} V(x, t) &= \max_{u_i \in [0, 1]} \left\{ \sum_{i=1}^n \lambda_i u_i [p_i + V(x-1, t+1)] \right. \\ &\quad \left. + (1 - u'\lambda) V(x, t+1) \right\}, \end{aligned} \quad (17)$$

with the boundary condition (3), which using the marginal value of capacity ΔV

becomes

$$\begin{aligned} V(x, t) &= \max_{u_i \in [0, 1]} \left\{ \sum_{i=1}^n \lambda_i u_i p_i - u'\lambda \Delta V(x, t) \right\} \\ &\quad + V(x, t+1) \quad (18) \\ &= \max_{0 \leq \rho \leq \sum_{i=1}^n \lambda_i} \{ R^a(\rho) - \rho \Delta V(x, t) \} \\ &\quad + V(x, t+1) \quad (19) \end{aligned}$$

where $\rho = u'\lambda$ and $R^a(\rho) = \max_u \{ \sum_{i=1}^n u_i \lambda_i p_i : u'\lambda = \rho, u_i \in [0, 1] \}$ is the maximum revenue rate when the capacity is consumed at a rate equal to ρ , and $u^a(\rho)$ is the corresponding control.

Proposition 6. *The capacity control problem (12) can be reduced to the dynamic programs (19) and (14) expressed in terms of the aggregate consumption rate ρ . In particular, if $\rho^*(x, t)$ denotes the optimal solution of Equations (19) and (14) and $u^*(x, t)$ denote the optimal policy for Equation (12), then $u^*(x, t) = u^a(\rho^*(x, t))$.*

A similar result was derived by Talluri and van Ryzin [13] for a capacity control problem for a model with customer choice.

A Unified Analysis of the Pricing and Capacity Control Problems

The preceding analysis illustrates that both problems can be reduced to “appropriate” single-product pricing problems, highlighting their common structure and enabling a unified treatment. As a starting observation, for both Equations (15) and (19), the optimal control $\rho^*(x, t)$ is computed from

$$\rho^*(x, t) = \arg \max_{\rho \in \mathcal{R}} \{ R(\rho) - \rho \Delta V(x, t) \},$$

where $R(\cdot)$ is a concave increasing revenue function. Using the properties of $R(\cdot)$, one gets that $\rho^*(x, t)$ is decreasing in $\Delta V(x, t)$, which using a backwards induction argument in t gives that $\Delta V(x, t)$ is decreasing in x and t . These standard results for single-product dynamic pricing problems are summarized below; a proof can be found in [10] (Proposition 5.2 Chapter 4).

Proposition 7 [10, Proposition 5.2 Chapter 4]. *For both problems defined in Equations (1) and (12), we have that:*

1. $\rho^*(x, t)$ is decreasing in the marginal value of capacity $\Delta V(x, t)$, and
2. $\Delta V(x, t)$ is decreasing in x and t .

Structural results for the pricing and capacity allocation policies follow from the properties of R^r, λ^r , and R^a, u^a , respectively. For example, consider the pricing problem for the case where the products are nonsubstitutes, that is, the demand for product i is only a function of the price for that product p_i . In that case, the Lagrangian associated with Equation (16) is $L(\lambda, x, y) = R(\lambda) + x(\rho - \sum_{i=1}^n \lambda_i) - y'\lambda$, with first-order conditions given by $\partial R(\lambda)/\partial \lambda_i = x + y_i$, for some $x \geq 0$ and $y_i \leq 0$ with $y_i = 0$ if $\lambda_i > 0$. It is easy to show that x is decreasing in ρ (i.e., the shadow price for the capacity consumption constraint decreases as ρ increases), and that $\lambda_i^r(\rho)$ is decreasing in x .

Corollary 1. *Consider the problem specified in Equations (2) and (3) and further assume that the products are nonsubstitutes, that is, $\lambda_i(p) = \lambda_i(p_i)$ for all i . Then, $\lambda_i^*(x, t)$ is nondecreasing in $\rho^*(x, t)$ (and nonincreasing in $\Delta V(x, t)$).*

A similar result can be obtained when products are substitutable provided that the demand model satisfies certain conditions analogous to those of the sensitivity matrix B of the linear model described earlier in this section.

For the capacity control problem, it is easy to recover some well-known structural properties of the optimal policy; see Lee and Hersh [3]. Our derivation based on the capacity consumption rate offers new intuition as to why they hold. Specifically, $R^a(\cdot)$ is a knapsack solution for which

$$R^a(\rho) = \min_i c_i + p_i \rho \quad \text{and} \quad u_k^a(\rho) = \min \left(\frac{\left(\rho - \sum_{i < k} \lambda_i \right)^+}{\lambda_k}, 1 \right), \quad (20)$$

where $c_1 = 0$ and $c_i = \sum_{k < i} \lambda_k(p_k - p_i)$, and for any $x \in \mathbb{R}$, $x^+ := \max(x, 0)$, and the optimal control $\rho^*(x, t)$ reduces to the solution to $\max\{\min_i c_i + (p_i - \Delta V(x, t))\rho : 0 \leq \rho \leq \sum_{i=1}^n \lambda_i\}$. Let $i^*(x, t) = \max\{i \geq 1 : p_i \geq \Delta V(x, t)\}$. Then, by inspecting the form of the piecewise linear objective function involved in the calculation of $\rho^*(x, t)$, we get that $\rho^*(x, t) = \sum_{i \leq i^*(x, t)} \lambda_i$. That is, the solution is “bang-bang” in the sense that the form of the optimal control is such that $u_i^*(x, t)$ is 0 if $i > i^*(x, t)$ and 1 if $i \leq i^*(x, t)$. In addition, from Proposition 7 part 1, we see that $i^*(x, t)$ is decreasing in the marginal value of capacity $\Delta V(x, t)$. Therefore,

Corollary 2. *For the capacity control problem (12) or equivalently, Equations (19) and (3), the optimal allocation policy is nested in that $u_i^*(x, t) = 1$ if $i \leq i^*(x, t)$, and $u_i^*(x, t) = 0$ otherwise, and $i^*(x, t)$ is decreasing in the marginal value of capacity $\Delta V(x, t)$.*

Efficient Frontier. The subproblem of computing the optimal revenue subject to a constraint on the aggregate capacity consumption rate specified in Equations (16) and (20) defines an efficient frontier $(\rho, R^r(\rho))$ and $(\rho, R^a(\rho))$ for the dynamic pricing and capacity allocation problems, respectively. As in the context of portfolio optimization, the efficient frontier provides a systematic framework for comparing different policies and highlights the structure of the respective optimal controls. It may also lead to computational improvements if this subproblem can be solved efficiently, preferably in closed form. This is possible in some common demand models such as the linear and the multinomial logit. The preceding discussion is from [6]. The idea of an efficient frontier has also appeared and is discussed in more detail in Feng and Xiao [14,15] and Talluri and van Ryzin [13]. Finally, we note that the structure of the dynamic programs studied in this section has been observed in other papers, such as Lin *et al.* [16] and their study of single-resource capacity control problems where each arrival may request multiple units of capacity, and Vulcano *et al.*

[19] and their analysis of optimal dynamic auctions. The latter involves an analysis of a discrete-time, batch demand analog to the dynamic program studied here.

Solution to the Deterministic Multiproduct Pricing Problem

As before, the “fluid” model has deterministic and continuous dynamics, and is obtained by replacing the discrete stochastic demand process by its rate, which now evolves as a continuous process. The realized instantaneous demand for product i at time t is deterministic and is given by $\lambda_i(t)$. We allow product i requests to consume capacity at a rate of $a_i > 0$ units per unit of demand, and denote the vector $[a_1, \dots, a_n]$ by a . This is a generalization of the model considered thus far that assumed uniform capacity requirements (all equal to 1). With a general capacity requirement vector a , the capacity consumption rate is defined by $\rho = a'\lambda$, and the definitions of R^r and λ^r can be appropriately adjusted to reflect that change. The system dynamics are given by $X(t+1) = X(t) - \sum_{i=1}^n a_i \lambda_i(t)$, $X(0) = C$, together with the boundary condition that $X(T) \geq 0$. The firm selects a demand rate $\lambda_i(t)$ (or a price) at each time t . The fluid formulation of the multiproduct pricing problem is the following:

$$\max_{\{\lambda(t), t=1, \dots, T\}} \left\{ \sum_{t=1}^T R(\lambda(t)) dt : \sum_{t=1}^T a' \lambda(t) dt \leq C \right. \\ \left. \text{and } \lambda(t) \in \mathcal{L} \forall t \right\}. \quad (21)$$

Gallego and van Ryzin [2, Section 4.5] partially extended their single-product results to multiple products, but without providing such a succinct solution as the one presented in the previous section. An alternative approach that exploits the action space reduction described in the section titled “A Common Formulation in Terms of the Aggregate Capacity Consumption” was described in Ref. 6 and is reviewed below. Specifically, recalling the definitions of the aggregate revenue function $R^r(\rho)$ and optimal demand rate vector $\lambda^r(\rho)$ in Equation (16) adjusted for

the fact that $\rho = a'\lambda$, Equation (21) can be rewritten as

$$\max_{\{\rho(t), t=1, \dots, T\}} \left\{ \sum_{t=1}^T R^r(\rho(t)) dt : \sum_{t=1}^T \rho(t) dt \leq C, \rho(t) \in \mathcal{R} \forall t \right\}. \quad (22)$$

Note that Equation (22) is identical to a single-product problem with revenue function R^r , and thus is solvable using the approach described above. Let $\rho^0 := C/T$ and $\hat{\rho} = \arg \max_{\rho} R^r(\rho)$. Then, the optimal solution to Equation (22) is to consume capacity at a constant rate $\bar{\rho}$ given by

$$\bar{\rho}(t) := \min(\hat{\rho}, \rho^0) \quad \forall t, \quad (23)$$

the corresponding vector of demand rates is $\lambda^r(\bar{\rho})$, while the price vector is $p(\lambda^r(\bar{\rho}))$. A direct verification that this solution satisfies the optimality conditions for Equation (21) establishes the following:

Proposition 8. *Let $\bar{\lambda}(\cdot)$ and $\bar{p}(\cdot)$ denote the optimal vectors of demand rates and prices for Equation (21). Then, $\bar{\lambda}, \bar{p}$ are constant over time and are given by $\bar{\lambda}(t) = \lambda^r(\bar{\rho})$ and $\bar{p}(t) = p(\lambda^r(\bar{\rho}))$.*

Asymptotically Optimal Heuristics Extracted From the Deterministic Model

Finally, we discuss three heuristics for the revenue management problems studied in this section. For each of these policies, one could show that they achieve the optimal asymptotic performance in the spirit of the results of the section titled “The Fluid Model”; details of these arguments can be found in [6].

1. *The Static Pricing Heuristic of Gallego and van Ryzin [2].* This policy implements the static prices $\bar{p}$ specified in Proposition 8. (This is the “make-to-order” heuristic in [2].)
2. *A List Price Capacity Control (LPCC) Heuristic.* One way to implement Equation (25) is by introducing capacity control capability on top of the static

prices given in (1). Specifically, our second heuristic is defined as follows:

- a. price according to $\bar{p}$ and label products such that $\bar{p}_1/a_1 \geq \bar{p}_2/a_2 \geq \dots \geq \bar{p}_n/a_n$, and
- b. compute $\bar{\rho}(x, t)$ and use the capacity controls $u_1(x, t) = 1$ if $x > 0$, $u_1(0, t) = 0$, and

$$u_i(x, t) = \begin{cases} 1 & \text{if } \bar{\rho}(x, t) - \sum_{j < i} a_j \bar{\lambda}_j \geq 0 \\ 0 & \text{otherwise} \end{cases} \quad \text{for } i \geq 2. \quad (24)$$

Note that this policy can only reduce the aggregate capacity consumption rate from its nominal value of $\sum_{i=1}^n a_i \bar{\lambda}_i$, but can never increase it. A product is made available only if the fluid solution starting from that state would choose to sell this product in all future time periods, and “closes” the product if the fluid solution would dictate only partial acceptance of the associated demand.

This policy was described in [6]. It is a refinement of the static pricing policy in (1) and the make-to-order heuristic of Gallego and van Ryzin [2]. Other examples of joint pricing and capacity controls can be found in the recent papers by Vulcano *et al.* [19], by Lin *et al.* [16] and Feng and Xiao [15].

3. *A Dynamic Pricing Heuristic.* The solution of the fluid pricing problem of the section titled “Solution to the Deterministic Multiproduct Pricing Problem” can be described in feedback form as

$$\bar{\rho}(x, t) = \min \left(\hat{\rho}, \frac{x}{T-t} \right), \quad (25)$$

where x is the remaining capacity at time t . The third heuristic that we present translates the aggregate control $\bar{\rho}(x, t)$ into product-level rates

(and prices) through

$$\begin{aligned} \lambda(x, t) &= \lambda^r(\bar{\rho}(x, t)) \quad \text{and} \\ p(x, t) &= p(\lambda(x, t)), \end{aligned} \quad (26)$$

where the mapping $\lambda^r(\cdot)$ was the maximizer in Equation (16) and was continuous in ρ . This corresponds to the idea of “resolving” the fluid problem as we step through time, which has also been discussed in the section titled “Single-Product Dynamic Pricing Problem.” This is widely applied in practice, where, however, the resolving occurs at discrete points in time, for example, daily or weekly depending on the application setting. These resolving policies seem to have been first analyzed in Ref. 6. Specifically, the results in [6] show that the idea of resolving applied in the context of the dynamic pricing or the LPCC heuristics is fluid-scale asymptotically optimal, as is the static policy (1); the single-product version of this feedback pricing policy has also been studied by Reiman [20]. These results show that the suboptimal behavior demonstrated by a resolving policy in the negative example studied in Cooper [12] does not persist in systems with large capacity and large demand. Intuitively, our preceding discussion illustrates that “resolving” is nothing but implementing the fluid policy in the feedback form. Numerical experiments documented in many papers [6] demonstrate that such feedback heuristics tend to outperform policies that are “static.”

DYNAMIC PRICING NETWORK REVENUE MANAGEMENT PROBLEMS

Suppose that the firm is operating a network of resources, indexed by $j = 1, \dots, m$, and that each product i request consumes A_{ij} units of resource j capacity. Let $A := [A_{ij}]$ denote the associated capacity consumption matrix, and assume that the initial capacity for each resource j is C_j . Then, the fluid

model formulation of the network dynamic pricing problem is

$$\max_{\{\lambda(t), t=1, \dots, T\}} \left\{ \sum_{t=1}^T R(\lambda(t)) dt : \sum_{t=1}^T A\lambda(t) dt \leq C \right. \\ \left. \text{and } \lambda(t) \in \mathcal{L} \forall t \right\}. \quad (27)$$

As before, this problem can be expressed in terms of ρ , which is defined by $\rho := A\lambda$. Specifically, let

$$R^r(\rho) := \max_{\lambda} \{R(\lambda) : A\lambda = \rho, \lambda \in \mathcal{L}\}, \quad (28)$$

be the maximum achievable revenue rate when resource capacity is consumed at a rate ρ , and $\lambda^r(\rho)$ denote the corresponding vector of optimal demand rates. Then, Equation (27) can be reduced to

$$\max_{\{\rho(t), t=1, \dots, T\}} \left\{ \sum_{t=1}^T R^r(\rho(t)) dt : \sum_{t=1}^T \rho(t) dt \leq C \right. \\ \left. \text{and } \rho(t) \in \mathcal{R} \forall t \right\}. \quad (29)$$

Let $\bar{\rho}$ denote the solution to Equation (29). Then, $\lambda^r(\bar{\rho})$ is the vector of optimal demand rates for Equation (27). This reduction could prove computationally beneficial, since as is often the case the number of products (e.g., the number of fare-class and origin-destination pairs) tends to be greater than the number of resources (e.g., number of flights in a hub-and-spoke network). We refer the reader to Gallego and van Ryzin [2] and Kleywegt [21] for fluid formulations to multiproduct network revenue management problems.

EXTENSIONS

There are several extensions that we chose not to address in this article. Some may be the result of practical considerations. For example, one may want to consider pricing policies where the feasible price grid is discrete, say in \$10 increments. Feng and Xiao [15] have studied this problem. Another

extension would incorporate costs incurred when the price is changed; this problem was studied in Celik *et al.* [22].

Two other important research directions of practical and theoretical interest are the following. The first studies revenue maximization problems for which the seller does not have accurate information about the underlying demand model. In such settings, the seller uses its pricing decisions to simultaneously learn the demand and optimize revenues. The second studies the effect of strategic consumer behavior on revenue maximization practices, such as their intentional waiting for sale periods to make their retail purchases.

DYNAMIC PRICING UNDER CONSUMER REFERENCE-PRICE EFFECTS

HASAN ARSLAN

INTRODUCTION

Consumers have a memory of past prices of products that are repeatedly purchased. As consumers are exposed to prices of products over a period of time, they develop certain price expectations. These price expectations are called *reference prices* [1–3]. They become benchmark prices against which consumers compare the current prices of products before they purchase. Empirical studies on consumer purchasing behavior in the marketing literature indicate that consumers utilize past prices to form reference prices [4,5]. The notion that consumers form reference prices to evaluate product prices is an application of the psychological theory of adaptation-level formation [6]. Reference prices, thus, are used as adaption levels for the observed prices [7].

Many articles have been written in the marketing literature on how reference prices influence consumers' purchasing decisions, how reference prices are formed, and how reference prices can be measured. Winer [8] reviews the theoretical foundations and modeling of the reference-price concept. Kalyanaram and Winer [9] survey the literature and propose empirical generalizations from reference-price research to support the reference-price concept. Briesch *et al.* [10] provide an empirical comparison of different reference-price models in the marketing literature. Mazumdar *et al.* [11] review the marketing literature on reference price in

both the behavioral and modeling areas and identify the unresolved issues.

The concept of reference price asserts that consumers make purchasing decisions for products with repeated purchases based on both observed and perceived prices. If the observed price of a product is below (above) the reference price, consumers perceive gains (losses) and purchasing becomes more (less) attractive [7,12–17]. Price promotions lower reference prices for future purchases. Thus, consumers may not perceive future price promotions as a good deal as the earlier ones. Consumers may perceive increase in prices when price promotions are over. Kalwani and Yim [5] report that the price consumers expected to pay for a product was significantly lower after they observed either more frequent or deeper promotions for the product on the prior purchase occasions. Also, an excessive use of promotions would confuse consumers. Consumers would perceive a return to the regular price as a price increase. Thus, there is an optimal frequency and amount of promotions that does not lower the reference price significantly nor confuses consumers about the regular price [9].

Firms are not able to directly modify how consumers form reference prices. However, they can influence reference prices through dynamic price patterns. Firms can develop more informed dynamic pricing strategies by taking consumer reference-price effects into account [18]. Our objective in this study is to explore the current-state of literature on how dynamic pricing models incorporate consumer reference-price effects in developing more informed dynamic pricing strategies for products that have repeated consumer interactions. We limit our review to studies where the reference-price concept is incorporated into dynamic pricing models. We use the following four-step framework for our review of the literature. First, we describe the effects of reference prices on consumer demand and purchasing decisions. Second, we present the formation process of reference prices. Third, we review the major dynamic

pricing models and some of their extensions in the presence of consumer reference-price effects. Finally, we identify research gaps and provide directions for further research on dynamic pricing area in the presence of consumer reference-price effects.

REFERENCE-PRICE EFFECTS ON CONSUMER DEMAND

The impact of reference price on demand is behaviorally explained at the individual level by the “prospect theory” [19]. The objective of prospect theory is to describe or predict consumer behavior under reference-price effects. Prospect theory posits the following: (i) consumers code the observed price of a product as loss or gain, depending on whether it is greater than or less than the reference price, respectively; (ii) consumers are asymmetric in their response to the observed price such that they are more sensitive to the prospect of a loss than to the prospect of a gain. Reference-price effects are considered to be asymmetric if consumers’ responsiveness to a positive difference between a reference price and a purchase price (i.e., a gain) is not the same as their responsiveness to a negative difference (i.e., a loss).

Symmetric Reference-Price Effects

There are many empirical studies in the marketing field that analyze reference-price effects on consumer demand using panel data. Reference-price effects on consumer demand is estimated by comparing a consumer demand model that contains no reference price with a model that incorporates reference-price term. Winer [7] observes through empirical testing that the discrepancies between reference prices and observed prices strongly affect consumers’ both product and quantity choices. Winer [7] is the first to propose a symmetric “sticker shock” model of reference price. According to his model, consumer utility from purchasing a good not only depends on the observed price but also on the difference between the reference price and the observed price. He assumes that a positive (negative) difference between the reference price and the observed

price increases (decreases) consumer utility from the product. Furthermore, he assumes that consumers’ response to a positive and a negative difference is symmetric. Winer [7] suggests that a firm’s optimal promotion policy over time should consider reference-price effects on consumer choice for frequently purchased products.

Asymmetric Reference-Price Effects

As indicated in Kalyanaram and Winer [9], further studies in the marketing field [12,13,15,20–22] provide empirical support for the following generalization for frequently purchased products: consumers react more strongly to price increases than to price decreases relative to the reference price—the notion that losses loom larger than gains.

Putler [15] is the first to derive the asymmetric reference-price demand model by formally integrating prospect theory into the traditional economic theory of consumer choice, thus providing a stronger theoretical base for the empirical results. His theoretical and empirical analysis indicate that reference prices have significant impact on consumers’ purchasing behavior and consumers react to losses (price increases relative to the reference price) more than gains (price decreases relative to the reference price)—consumers exhibit *loss aversion*. Hardie *et al.* [22] also study the asymmetric reference effects on consumers. They define that consumers perceive gains (losses) when price of a brand is less (greater) than that of the reference brand. They find that losses relative to the reference brand have more impact on consumer purchasing behavior than gains.

However, some studies in the marketing field find that consumers are not always more responsive to a loss than to a gain. Greenleaf [18], for example, finds that consumers may react less strongly to price decreases than price increases for frequently purchased products when consumers are exposed to either infrequent promotions or an irregular pattern of promotions. This result is in contrast to Kalyanaram and Little [12], Kalwani *et al.* [13], and Kalwani and Yim [5].

REFERENCE-PRICE FORMATION PROCESS

Modeling-based reference-price research uses consumer purchase history as the main determinant of reference price. Briesch *et al.* [10] and Mazumdar *et al.* [11] provide a summary of previously used reference-price models. The most commonly used reference-price model in the literature assumes that the reference price $r(t)$ in period t is an exponentially weighted average of prior prices $p(s)$, $s < t$ [12–15,18,23,24]

$$r(t) = \alpha r(t-1) + (1-\alpha)p(t-1). \quad (1)$$

Parameter $0 \leq \alpha \leq 1$ denotes the consumer memory effect of prior prices on reference price. Reference price becomes more dependent on past prices as the value of α increases. The lower the value of α is, the shorter the memory of consumers on prices is. Namely, if $\alpha = 0$, then the reference price equals to the past price. Empirical studies show that parameter α ranges approximately from 0.60 to 0.85. This indicates that prices experienced beyond two or three purchase occasions have negligible impact on reference price [25]. Consumer memory parameter is also an indicator of consumer shopping frequency. Thus, it can be used as a proxy for consumer loyalty [24]. Kopalle *et al.* [26] indicate that regression models can be used to estimate the value of parameter α . Equation (1) is also the most empirically validated reference-price formation process in the literature [7,18,24,26–28]. We illustrate the formation of reference prices in Equation

(1) on an example with consumer memory parameter $\alpha = 0.5$ in Fig. 1.

In continuous time, reference price at time t is modeled as a continuous weighted average of prior prices with an exponentially decaying weighting function [27–29], which can be represented by the following ordinary differential equation

$$\frac{dr(t)}{dt} = \alpha(p(t) - r(t)). \quad (2)$$

Consumers begin making purchasing decisions on a frequently purchased product with an initial reference price, $r(0)$. In all analytical models in the literature, the initial reference price is assumed to be an external parameter. There is no specific study focusing on identifying the drivers of initial reference price for newly introduced products. Thus, estimating initial reference price is an open research question to be considered. As consumers observe posted prices, they update their perceptions of the value of the product. Equivalently, the continuous reference-price formation in Equation (2) can be represented by the following formulation

$$r(t) = e^{-\alpha t} \left(r(0) + \alpha \int_0^t e^{\alpha s} p(s) ds \right). \quad (3)$$

Similarly, the discrete reference-price formation can also be written as a sum of weighted averages of prior prices.

Hardie *et al.* [22] provide an alternative reference-price formulation. They set a reference brand (rather than price) for consumers based on their purchase history. The reference price becomes the current price of

Figure 1. Exponential smoothing reference-price formation process, $\alpha = 0.5$.

the last brand bought—the reference brand. Consumers perceive gains (losses) from a brand when its price is below (above) the price of the reference brand. They also show that reference brand formation is empirically valid in a multibrand environment. Kopalle *et al.* [26] adapt the reference brand formulation in Hardie *et al.* [22] in determining the optimal dynamic pricing policy for a monopolist managing two brands as well as for a duopolist.

DYNAMIC PRICING MODELS UNDER DISCRETE AND CONTINUOUS TIME SETTINGS

The major managerial implications on dynamic pricing in the presence of reference-price effects are provided by Greenleaf [18], Kopalle *et al.* [26], Fibich *et al.* [28], and Popescu and Wu [24]. These studies investigate the impact of reference price on dynamic pricing strategies. The key managerial implication from these major studies is: firms can develop more informed dynamic pricing and price promotion strategies for frequently purchased products by considering how their past pricing patterns impact the current demand, and thus they should consider the impact of reference-price effects in developing their dynamic pricing and promotion policies. We next review the above major studies and some of their extensions that develop analytical models to explore optimal dynamic pricing strategies for firms in the presence of reference-price effects.

Base Model

Greenleaf [18] studies both analytically and empirically how reference-price effects influence promotion profits. He indicates that retailers cannot directly control how consumers form reference prices; however, they can indirectly control reference prices through changing the price pattern that consumers observe over time. The existing literature [7,13,15,17] before Greenleaf [18] focused on describing how consumers form reference prices and testing how reference prices affect consumer demand. Greenleaf [18] is the first to analyze the impact of

reference prices on developing promotion strategies.

Greenleaf [18] considers a single retailer who promotes a single brand over a finite number of time periods. The objective of the retailer is to estimate how the reference-price effects generated by the promotion impact the profits. Thus, the retailer maximizes the net present value of brand profits generated by the pricing decisions. His model does not analyze cross-brand profit effects and does not consider competition among different brands. He assumes the following reference-price formation, which is an extension of the discrete reference formation in Equation (1):

$$r(t) = \alpha r(t-1) + (1-\alpha)p(t-1) + \gamma(t); \quad (4)$$

where $r(t)$ is an error term with expected value of zero. He also assumes that the retailer faces the following demand for the brand in period t

$$d(r(t), p(t)) = q(p(t)) + \delta(r(t) - p(t)) + \varepsilon(t) \text{ if } r(t) > p(t), \quad (5)$$

$$d(r(t), p(t)) = q(p(t)) + r(r(t) - p(t)) + \varepsilon(t) \text{ if } r(t) > p(t), \quad (6)$$

where $q(p(t))$ is the demand in the absence of reference-price effects while the remaining part reflects the reference-price effect on demand and $\varepsilon(t)$ is an error term. He assumes that $q(p(t))$ is linearly decreasing in price $p(t)$. The demand model in Equations (5)–(6) assumes that in the absence of reference-price effects the product demand $q(p(t))$ is linearly decreasing in price; the reference-price effects are linear in $p(t) - r(t)$; reference-price effects are additive; consumers perceive gains when $p(t) < r(t)$; consumers perceive losses when $p(t) > r(t)$; reference-price effects are asymmetric (consumers are loss-seeking or loss-averse or risk-neutral when $\delta > \gamma$ or $\delta < \gamma$ or $\delta = \gamma$, respectively).

His single promotion model explains how reference-price effects impact promotion profits of the retailer. He extends the single period model to multiple periods using dynamic programming to analyze the impact of reference prices on recurring promotion strategies. The recurring promotion policies

prescribe when the retailer should promote and what promotion price the retailer should charge. He analyzes the optimal promotion policies numerically for a brand of peanut butter sold by a supermarket chain. His main findings from this numerical study are the following:

- Gains have higher impact on demand than losses. $\delta > \gamma$ (loss-seeking consumers).
- Repeating cycles of profitable promotions can occur when consumers are loss-seeking. In these promotions, the nonpromotion price is charged at least half of the time. In repeating promotion cycles, promotions are followed by regular prices.
- Repeating cycles of profitable promotions can also occur when consumers are loss-averse or risk-neutral. In these promotions, the retailer charges the regular price less than half of the time and the demand at the regular price is zero. These are called *reverse promotions*.

In reverse promotions, the only purpose of charging the high regular price is to raise consumers' reference prices. This implies that it would be better for the retailer to completely sacrifice the demand during the periods of high price in order to raise reference prices and generate greater demand during the periods of low price. The same result is also derived in Fibich *et al.* [30] in a continuous time setting. This result is very surprising since almost all price promotions in practice involve a price reduction and not a price increase. We have to keep in mind that this result is only valid when losses have an equal or greater impact than gains, which was empirically observed only in Greenleaf [18] and Murthi and Kalyanaram [31]. Most empirical studies in the literature, however, suggest that gains have an equal or greater impact than losses [7,14].

Greenleaf [18] also observes that increasing consumer memory parameter has two opposite impacts on promotion profits. When it is higher, reference prices increase more slowly after a promotion. Therefore, more time must elapse before the reference price is

again high enough to create a large reference-price effect that makes promotions profitable if the impact of gains is higher than that of losses. Since profitable promotions occur less frequently, promotion profits decrease. Promotion profits may also increase with consumer memory parameter. When reference prices change more slowly, the retailer has more control over which precise reference price to choose for starting a new promotion. This allows the retailer to select a reference price closer to the one that maximizes promotion profits. This observation supports the managerial importance of estimating consumer memory parameter in developing more profitable promotion policies. He also observes that irregular promotions often maximize profit from reference-price effects. He thus recommends managers to avoid regular promotion timing so that consumers would not strategize the timing of promotion deals. Optimal pricing policies in Greenleaf [18] are summarized in Table 1. Greenleaf [18] concludes that reference-price effects impact promotion profits. Thus, retailers should not ignore reference-price effects and should develop promotion strategies that allow reference-price effects to increase profits.

Discrete Time Setting

The objective of Kopalle *et al.* [26] is to generalize the results in Greenleaf [18]. They extend Greenleaf's result analytically for a single brand in a monopolistic setting where all customers are homogeneously either loss-averse or loss-seeking. They use this setting as a building block to analyze a monopolist retailer with multiple brands. They first consider a monopolist firm that maximizes the sum of discounted profits over an infinite time horizon for a single brand. They assume that prices are bounded. They also assume that the reference price in each period is an exponentially weighted average of past observed prices as we explain in Equation (1). Following Greenleaf [18], they assume that the demand in period t is $d(r(t), p(t))$ as in Equations (5)–(6), without the error term $\varepsilon(t)$. They assume that $q(p(t))$ is continuous and differentiable. They use a dynamic programming model to determine the optimal

^aRefs 18, 24, and 26.

pricing policy for a given value of initial reference price. They derive the following three main results for the monopolist firm:

- If all consumers are loss-seeking $\delta > r$, it is optimal for the monopolist to vary prices over time.
- If all consumers are risk-neutral $\delta = r$, the optimal pricing policy monotonically converges to a constant steady-state price.
- If all consumers are loss-averse $\delta < r$ and the consumer memory parameter $\alpha = 0$, then the optimal pricing policy monotonically converges to a constant steady-state price.

On the basis of the above three main results, they conjecture that the optimal pricing policy for a monopolist firm with a single brand monotonically converges to a constant price when consumers are either risk-neutral or loss-averse. They examine this conjecture numerically using linear and nonlinear $q(p(t))$ functions that have empirical support in the marketing literature. Their numerical findings indicate that the optimal pricing policy maximizing either the sum of discounted profits or average profit per period monotonically converges to a constant steady-state price. They extend their model to a monopolist firm with multiple brands. They assume

that each brand forms its own reference price independently using only its own prior prices. They derive the following three main results for the monopolist firm selling multiple brands:

- If all consumers are loss-seeking $\delta > r$ for all brands, then at least one brand must have a cyclical pricing policy when the sum of discounted profits over an infinite horizon is maximized.
- If all consumers are loss-seeking $\delta < r$ for all brands, then all brands have cyclical pricing policies when the average profit per period is maximized.
- If all consumers are loss-averse $\delta < r$ for all brands, then a constant price for all brands is more profitable than cyclical prices for any brand when the average profit per period is maximized.

Kopalle *et al.* [26] also consider a duopoly case in which two brands compete with each other. Each brand maximizes its own average profit per period. Reference-price effects of each brand are independent from one another. The only interdependency between the two competing brands is the cross-price effect. They derive the following four main results for the duopoly case:

- If each brand decides to maintain cyclical prices, the equilibrium strategy is to offer cyclical prices.
- If consumers are loss-seeking, the equilibrium strategy is to offer cyclical prices.
- If consumers are loss-averse, a constant price policy performs better than a cyclical pricing policy.
- If consumers are loss-seeking toward the first brand, whereas they are loss-averse towards the second brand, in equilibrium the prices of the first brand should cycle while the second brand should maintain a constant price.

Kopalle *et al.* [26] also investigate using simulation on how their results depend on the specific reference-price formation process—exponential smoothing process. They use an alternative reference formation process, an aggregate version of the *reference brand* formation process in Hardie *et al.* [22], to check robustness of their results. Under this alternative reference formation, the reference price is the current price of the last brand purchased (called the *reference brand*) by consumers. They simulate both a monopolistic retailer with two brands and a duopoly case under the reference brand formation process. For the monopolist retailer with two brands, they observe that constant (cyclical) pricing policy is optimal for both brands when consumers are loss-averse (loss-seeking). These observations on pricing policies are the same as those under the exponential smoothing process. They also observe that a constant pricing policy is optimal for both brands when consumers are loss-seeking for one brand and loss-averse for the other brand. This observation is in contrast to the corresponding one for the monopolist retailer with two brands using the exponential smoothing process. For the duopoly case, their numerical findings indicate that a constant pricing policy is optimal for both brands when consumers are all either loss-seeking or loss-averse. They also observe that a constant pricing policy is still optimal when consumers are loss-seeking for one brand and loss-averse for the other. Under the reference brand

formulation, pricing decisions of each brand impact the other through cross-price effect and reference-price effect. Thus, neither brand can increase its demand by executing cyclical pricing policies. Under the exponential smoothing process, however, consumers select a brand in any period independent of their prior choices. Thus, brands can increase their demands by executing cyclical prices.

Finally, Kopalle *et al.* [26] consider heterogeneous consumers through segmenting the market into two: loss-seeking consumers (segment 1) and loss-averse consumers (segment 2). Their goal is to determine what percentage of the market should be segment 1 in order for cyclical pricing policies to be optimal—called as *critical ratio*. They derive a sufficiency condition for the critical ratio in order for cyclical pricing policies to be optimal in a single brand monopoly, a symmetric multibrand monopoly, a symmetric duopoly, and a symmetric oligopoly under an exponential smoothing process of reference-price formation. They also numerically explore the critical ratio for the reference brand formation process. Their analytical and numerical findings conclude that a relatively small value of critical ratio leads to cyclical pricing policies to be optimal in all cases when there is a homogenous market with only loss-seeking consumers. Optimal pricing policies in Kopalle *et al.* [26] are summarized in Table 1.

Continuous Time Setting

Similar to Kopalle *et al.* [26], Fibich *et al.* [28] extend the model in Greenleaf [18] to a competitive pricing setting in a duopoly environment. They develop a new method for the determination of optimal pricing strategies explicitly for firms that experience reference-price effects. They adapt the demand function $d(r(t), p(t))$ in Greenleaf [18] in Equations (5)–(6) for a single product in the continuous environment. They model the reference price in continuous time as a continuous weighted average of past prices with an exponentially decaying weighting function as we outline in detail in Equation (3), which can also be represented through the ordinary differential equation as we explain in Equation (2).

They consider a two-stage method to derive the optimal pricing policy explicitly in the presence of asymmetric reference-price effects. In the first-stage, they consider the symmetric reference-price effects $\delta = r$. Using variational optimization tools, they derive an explicit expression for the optimal pricing strategy for the monopolist. The models in Greenleaf [18] and Kopalle *et al.* [26] use a discrete time approach, thus the resulting dynamic programming models become hard to solve for explicit optimal pricing policies. The continuous-time approach by Fibich *et al.* [28] thus has the advantage over these earlier studies. In the second stage, they consider the asymmetric reference-price effects. They show that the solution for the asymmetric case is equivalent to an appropriately chosen solution for the symmetric case. This result is extremely useful. It provides the optimal pricing strategy for the asymmetric case, for which standard optimization techniques do not apply due to the nonsmoothness of the profit function. One can simply use the solution for the symmetric case to construct a solution for the asymmetric case. In summary, the two-stage method is: (i) determine explicitly the optimal pricing strategy for the symmetric reference-price effects, and (ii) use the solution in (i) to construct the optimal pricing strategy for the asymmetric reference-price effects.

They also show that the initial pricing strategy depends on whether the initial

reference price is higher or lower than the steady-state optimal price when the planning horizon is infinite as depicted in Fig. 2:

- If the initial reference price is lower than the steady-state price, then the penetration price is set lower than the steady-state price. During the introductory stage, the price increases monotonically and approaches to the steady-state price (penetration strategy).
- If the initial reference price is higher than the steady-state price, then the initial price is set higher than the steady-state price. During the introductory stage, the price decreases monotonically and approaches to the steady-state price (skimming strategy).

They show that the optimal price reaches to the steady-state value after the introductory stage for the infinite planning horizon case. They also derive the optimal pricing strategy explicitly for the finite planning horizon case. They show that the introductory stage has either penetration or skimming strategy; the introductory stage is followed by a steady-state pricing strategy; and toward the end of the planning horizon optimal price decreases since there is no need to make long-term reference-price planning. In summary, the optimal pricing strategy has

- a short introductory stage in which the initial reference-price value determines

Figure 2. Optimal pricing policies in Fibich *et al.* [28].

- whether there is an initial decrease (skimming) or increase (penetration) in price,
- a steady-state region in which the price is constant when the planning horizon is infinite,
- an additional short final decline stage when the planning horizon is finite.

The above results on the optimal pricing strategy heavily depend on the value of the initial reference price. However, there is no detailed discussion in Fibich *et al.* [28] on how the initial reference price can be estimated. This is an open research question that would be investigated in detail.

Fibich *et al.* [28] extend the model to the oligopolistic Cournot competition among multiple firms in which each firm may have a different unit production cost and decision variables are the firms' production levels. They consider both an open-loop and closed-loop Nash equilibrium. Using the two-stage method (developed for the monopoly case), they derive the open-loop equilibrium strategies explicitly for both the risk-neutral $\delta = r$ case and loss-averse case $\delta \leq r$ when the planning horizon is infinite. They show an interesting result that both the open-loop and closed-loop equilibrium strategies are qualitatively the same as in the monopolistic case, that is, skimming and penetration strategies in the introductory stage and converging to steady-state pricing strategy in the long run. Thus, they conclude that open-loop and closed-loop competition do not add new qualitative features to the model (i.e., they do not lead to cyclical pricing strategies).

To measure the impact of the optimal pricing strategy, they compare the optimal pricing strategy in the presence of reference-price effects with the following three alternative (suboptimal) pricing strategies

- *Pricing Strategy with No Reference-Price Effects.* The firm ignores the reference-price effects in developing the optimal pricing strategy (the optimal price is constant under the no reference-price effects).
- *Myopic Price Strategy.* The firm takes reference-price effect into account, however, follows a myopic approach; the firm develops the optimal pricing strategy that maximizes the instantaneous profits.
- *Optimal EDLP (Every Day Low Price) Strategy.* The firm chooses a constant optimal pricing strategy throughout the planning horizon.

They derive three main results in the comparison. First, the differences in profits among the optimal pricing strategy, optimal pricing strategy with no reference-price effects, and optimal EDLP strategy are very small. Firms, thus, can obtain near optimal profits using EDLP strategy. The analysis in Fibich *et al.* [28] thus provides a strong support for the EDLP strategy. Second, the myopic pricing strategy may result in substantially lower profits compared to the optimal pricing policy with no reference-price effects. Third, the optimal steady-state price is slightly below the optimal price in the absence of reference-price effects. They validate these three results through an empirical study using the data from Greenleaf [18] for a brand of peanut butter sold by a supermarket chain.

EXTENSIONS

Generalized Consumer Demand

Following Greenleaf [18], Popescu and Wu [24] treat the problem of consumers with memory and asymmetric reference-price effects in a discrete time setting using dynamic programming techniques to characterize dynamic pricing strategies for a frequently purchased product. Their objective is to extend the models in Greenleaf [18], Kopalle *et al.* [26], and Fibich *et al.* [28] using very general modeling assumptions on consumer demand. Greenleaf [18], Kopalle *et al.* [26], and Fibich *et al.* [28] use the demand model with piecewise linear reference-price effects in Equations (5) and (6), which limits the applicability of their results. Also, different from Fibich *et al.* [28], they provide structural results on optimal

pricing strategies rather than parametric results. Thus, Popescu and Wu [24] extend and generalize the models used in Greenleaf [18], Kopalle *et al.* [26], and Fibich *et al.* [28].

They consider a discrete-time model in which a monopolist repeatedly interacts with homogenous consumers over an infinite time horizon. In each period, the monopolist decides what price to charge from a bounded positive price interval. They assume a general reference-price dependent demand which is decreasing in price and increasing in the reference price. In each period, consumers update their current reference price through the exponential smoothing reference-price formation process in Equation (1). The objective of the monopolist is to choose prices in each period to maximize its discounted sum of long-term profits (over an infinite planning horizon) for a given value of initial reference price. Popescu and Wu [24] construct a dynamic programming model to analyze the optimal pricing path for the monopolist with the reference price as the state variable. More specifically, their objective is to determine when a steady-state solution exists for this dynamic programming model and to characterize stability and monotonicity properties of the optimal price and reference price paths.

They first analyze the case when consumers are risk-neutral (i.e., the reference-price effects are symmetric). For the risk-neutral case, they characterize the convergence of the optimal prices to a unique steady-state optimal price. They next extend their analysis to explore the transient and the steady-state behavior of the optimal dynamic pricing strategy when consumers are loss-averse as predicted by the prospect theory. They characterize the convergence of the optimal prices to a unique steady-state optimal price. Optimal pricing policies in Popescu and Wu [24] are summarized in Table 1. They derive a list of alternative sufficiency conditions in order for all optimal pricing paths to converge monotonically to the unique steady-state price. With these sufficiency conditions, they show that there are only three optimal pricing strategies: penetration strategy, if initial reference price is low (begin with charging a low

price and keep increasing it over time); skimming strategy, if initial reference price is high (begin with charging a high price and keep decreasing it over time); and constant pricing strategy. They derive the following structural results on the optimal pricing policies:

- An optimal steady-state price exists if consumers are either risk-neutral or loss-averse.
- If consumers are loss-seeking, there is no steady-state pricing strategy—the optimal pricing policy is cyclical. Kopalle *et al.* [26] obtain the same result when reference-price effects are piecewise linear. Greenleaf [18] also shows numerically that in the presence of reference-price effects, the optimal pricing policy for a monopolist can be cyclical.
- The optimal prices converge to a steady-state price after a transient stage.
- Optimal steady-state price decreases with α , the consumer memory parameter.
- As consumers become more loss-averse, the range of optimal steady-state prices becomes wider, that is, increasing pricing flexibility.
- Optimal reference prices follow a monotonic trajectory.
- Optimal prices follow a monotonic trajectory if consumers are very sensitive to reference-price effects or they have a short-term memory of past prices.

They also compare the pricing strategies of two firms for which consumer memory evolves according to the same process starting with the same initial reference price. One firm (myopic firm) ignores the effect of current prices on future demand, thus applies a myopic pricing policy, whereas the other firm (optimizer) considers the impact of current prices on future demand in developing its pricing policy. They show that the myopic firm systematically charges lower prices than the optimizer firm. This result is driven by the assumption that the profit function is supermodular in price and reference price.

By charging higher prices, the optimizer firm increases its future profits through increasing the reference price.

Popescu and Wu [24] enrich the state of the literature on dynamic pricing with reference-price effects by developing a very general nonlinear reference-price-dependent demand model that considers the dynamics of reference-price effect in response to changes in the reference price. Popescu and Wu [24] confirm the results of the steady-state analysis of the optimal pricing strategy in Kopalle *et al.* [26] and Fibich *et al.* [28], but not necessarily monotonicity of the transient pricing policy. Their approach is similar to the two-stage method in Fibich *et al.* [28]. Their technical contributions are characterization of the optimal steady-state prices, and convergence and monotonicity properties of the optimal pricing strategy. Their methodological contribution is to provide a new method (similar to the two-state method of Fibich *et al.* [28]) of proving structural properties for dynamic programming models with kinked rewards.

MULTIPRODUCT DYNAMIC PRICING

Calicchio and Krell [32] find that a surprisingly small number of products (less than four on average) account for half of the information customers use to determine their perceptions of a store's price level. These products are usually the generic and most commonly used household items. Asvanunt and Kachani [33] refer to these as the *core* products. They argue that considering core products has important pricing implications for retailers. They show that a retailer can price its core products competitively in order to improve the customers' perception of their store's price level and to lure more customers to shop at the store. The economics literature models competition through assuming that the demand of a product is a function of both its competitor's price and its own price. Asvanunt and Kachani [33] develop an alternative model (the concept of store reference price) where the retailers compete through customer's perception of their stores' price levels. They first consider the optimal dynamic pricing policy in discrete time

for a monopolist retailer offering multiple products, where the monopolist has the objective of maximizing its revenue over an infinite time horizon. They use the following reference-price formulation

$$r(t) = \alpha r(t-1) + (1-\alpha)\lambda'p(t-1), \quad (7)$$

where λ is a vector of nonnegative weights and $\lambda'p$ as the weighted average price of the retailer's products—the current store's price level. They assume that the demand for a product has the following form

$$d(r(t), p(t)) = q(p(t)) + \lambda(r - \lambda'p), \quad (8)$$

where $q(p(t))$ is linearly decreasing in price $p(t)$.

They derive a closed-form solution of the optimal pricing policy for a monopolist selling a single product. Their approach in discrete time yields the same expression of the steady-state reference price as in Fibich *et al.* [28]. They also prove in discrete time the same monotonicity and convergence results as in Fibich *et al.* [28]. It is interesting to point out that the optimal policy in discrete time is a function of the state that is the current level of the reference price, and is much more practical than the continuous-time solution, which was provided as a function of time in Fibich *et al.* [28]. They extend their results to multiple products and show that the monotonicity and convergence results still hold. They find that for otherwise identical products, the steady-state price of a core product is lower than that of a noncore product.

They next extend their model to a duopoly case in which two competing retailers offer the same two products to consumers. They derive the optimal pricing policy for a retailer when (i) its competitor's price is constant, (ii) its competitor's price is a linear function of the retailer's own price, and (iii) its competitor follows a myopic pricing policy (only maximizing the current revenue). They also illustrate how their framework can be extended for a duopoly in which each retailer offers identical multiple products, and how a similar closed-form heuristic may be obtained.

Dynamic Pricing with Product Introduction Decisions

Arslan *et al.* [34] consider a firm's decision on the product introduction timing and dynamic pricing for successive product generations in the presence of reference-price effects. They analyze the case where a firm introduces multiple generations of a product, for which demand is impacted by the reference price formed by consumers' shopping experience. Their model is based on the dynamic pricing model in Arslan *et al.* [35].

They focus on developing dynamic pricing and product introduction policies for two successive product generations—a base product and a new product. They use the demand functions in Equations (5)–(6), with symmetric reference-price effects. They also assume that reference price for each generation is formed through continuous weighted moving average of past prices with exponentially decaying weighting function as in Kopalle *et al.* [23] and Fibich *et al.* [24]. They consider two scenarios: complete replacement of the old product by the new one, and the case of generations offered concurrently. For the complete replacement case, they define the reference price for the new product recursively through base product's reference price and posted price. For the case of coexisting generations, they consider three cases of how reference prices evolve. In the first case, similar to the reference-price dynamics in complete replacement, reference prices of the concurrent product generations only share a common past, but evolve independently at present. In the second case, they assume that the firm considers a joint reference price for product generations. Each generation contributes to the joint reference price with a relative weight that measures how consumers are impacted by different existing product generations in forming their perceptions. In the third case, concurrent generations form the joint reference price as in the previous case; however, the two generations internally compete with each other. This case is applicable to products that are offered by competing divisions with different revenue objectives within the same firm.

They characterize the product introduction timing and pricing strategies explicitly

for two successive product generations, and propose a quasi-analytic solution method, based on the structure of the memory-dependent problem, for an arbitrary number of generations. They show that the total profit function and its derivatives are quasipolynomial functions in introduction time. They also compute the derivative of the profit function with respect to introduction time, which is subsequently used to determine the optimal introduction time. They show that the sign of this derivative depends on profit contribution margins of the base product and the new product. They observe that, as consumers become sensitive to reference-price effects, optimal introduction time shifts toward the less profitable product. They indicate that optimal introduction time as the root of the quasipolynomial profit function is not available in closed-form; however, they show that it can be calculated as a first-order correction to its corresponding no consumer memory value since an explicit expression for the derivative of the introduction time with respect to reference-price sensitivity is already derived. Their numerical experiments show that such an approximation performs very well. They show that as consumers become more sensitive to the reference-price effects, then firms gain more in profits. They extend their analysis to a duopoly environment in which two firms compete with each other, derive the Nash equilibria for the duopoly game, and illustrate how reference-price effects influence the Nash equilibria.

Dynamic Pricing with Product Innovation Decisions

Arslan *et al.* [36] study the competition among firms that produce and sell short life cycle products to consumers who are segmented in terms of price sensitivity and their purchasing behavior toward new and innovative products. Their objective is to derive insights on how pricing and product innovation strategies impact these firms' market positioning. They assume that the market demand for a newly introduced short life cycle product responds to two main factors: deviation of the product's own price from a marketwide reference price and deviation

of the product's innovation (manner) level from the current market average.

They assume that consumers evaluate attributes of past products to form a reference innovation level that affects their current perceptions on how innovative new products and firms are. They assume that consumers determine the reference product innovation level through a "mental calculation" of the average rate of product improvements or the average rate of new product introductions in the market. According to their model, consumers compare a product's current attributes or a firm's current innovation rate with their formed perception of the product innovation level in the market to determine their perceived gains and losses from purchasing the current product. Consumer demand increases (decreases) as consumers perceive gains (losses).

They assume that the reference product innovation level effects on consumer demand are linear; the reference product innovation level effects are additive; and the impact of perceived gains and losses through reference product innovation level effects on consumer demand is symmetric.

They formulate pricing and product innovation strategies in a differential game model. Their model measures the joint impact of reference prices and reference innovation levels in formulating optimal pricing and innovation strategies for competing firms. They incorporate the inherent diversity in consumer demand by characterizing consumers in terms of their sensitivity to product innovation (fashion) levels and product prices. They also characterize different types of firms in the market in terms of their pricing and innovation strategies. They are the first to consider reference memory effects of product innovation.

They derive the optimal pricing and innovation strategies for firms in a competitive environment. They show that the solution for the duopoly game under open-loop strategies is a linear combination of exponentials. They extend their analysis to an oligopoly game with N competing firms and derive the corresponding open-loop Nash equilibria. They consider two special cases of firms: discounter firms that control their pricing

policy while keeping their product innovation level constant and innovation-oriented firms that control their product innovation policy while executing constant pricing policy. They also analyze specific competition among firms that adhere to different types of pricing and product innovation strategies and derive the corresponding open-loop Nash equilibria in these settings. They derive the optimal pricing policy for a pure discounter firm under both monopoly and duopoly settings. They also derive optimal product innovation policies for pure innovation-oriented firms in a duopoly environment. They analyze the competition between a pure discounter firm and a pure product innovation-oriented firm. They determine optimal pricing and product innovation strategy for a firm that competes with a rival that executes both constant pricing and product innovation policies. They also show that the difference between closed-loop Nash equilibria and open-loop Nash equilibria is small, at least for reasonably low values of demand sensitivity parameters.

They consider a case study in the fast-fashion retail industry, to illustrate how their differential game model is applied in an environment with firms executing different pricing and product innovation strategies to compete. For example, they consider a game between fast-fashion clothing retailer Inditex and its competitor H&M. Inditex has the ability to introduce new products very fast (the average shelf-life of a product is as low as 24 days). Since they replace the products very quickly, they do not have the time to focus on price discounts. Thus, they choose product innovation as their main competitive strategy. H&M, on the other hand, does not have the ability to replace its products as fast as Inditex does. They have longer shelf-life for their products. Therefore, they utilize price discounts as their main marketing strategy. Another competitor type is a large department store that follows a hybrid strategy. It replaces products faster or provides more options to consumers in terms of product variety. At the same time, it also applies heavy price discounting. For such competitors, we develop a symmetric equilibrium and compare it against less elaborate strategies that focus on only product innovation or price

discounting. Their findings in the case study suggest that a hybrid strategy, which puts emphasis on both pricing and innovation, is optimal. Thus, they suggest that any comprehensive decision tool to determine pricing and product development (innovation) strategies should seek to integrate both reference price and reference product innovation level effects. Their conclusions are also confirmed by an extensive empirical study of new products' performance in the manufacturing sector by Carbonell and Rodriguez [37].

Price Negotiation

Huh *et al.* [38] extend the model in Kopalle *et al.* [26] and Asvanunt and Kachani [33] to a setting in which consumers are offered two separate prices. They classify consumers into two classes depending on how they form their reference prices: price-takers and price-hagglers. Price-takers form their reference prices through exponential smoothing reference-price process as in Equation (1). Price-hagglers, on the other hand, consider the price offered to price-takers as their reference price, similar to Hardie *et al.* [22]. They assume that demand from price-takers depends on both the posted price and the reference price, whereas the demand from price-hagglers depends on the price offered to them and how much this price deviates from the price offered to price-takers. Thus, they assume that price-takers do not have memory of past prices; instead they choose the current price offered to price-takers as of their reference price. They assume that demand functions are linear in posted prices and reference-price effects are linear. They also assume that consumers are loss-neutral (i.e., reference-price effects are symmetric).

They construct a dynamic programming model in which a monopolist retailer chooses its optimal pricing policy for price-takers and price-hagglers to maximize its revenues from a single product over an infinite planning horizon. They derive the closed-form solution for the optimal pricing policies for the monopolist. They also prove the monotonicity and convergence results of the optimal pricing policies. They extend their model to a duopoly setting, similar to the one introduced

by Asvanunt and Kachani [33], in which the competition occurs through the reference-price effect and consumers use a weighted average of prices offered by both firms to form their reference price. They show that monotonicity and convergence results hold true for the duopoly setting when one of the retailers follows a suboptimal policy—a constant pricing policy, a markup (down) pricing policy, or a myopic pricing policy (maximizing current period revenue). They provide a numerical method to calculate equilibrium pricing policies when the equilibrium policies are of linear form. They also perform a numerical analysis to measure the value of offering two separate prices to consumers by comparing their numerical results to those in Asvanunt and Kachani [33].

Peak-End Consumer Anchoring

Nasiry and Popescu [39] study the impacts of a new memory-based reference-price formation, based on a peak-end memory model of Fredrickson and Kahneman [40], on dynamic pricing policies with reference-price effects. This new memory-based reference-price model suggests that consumers develop a reference-price based on a weighted average of the lowest and the most recent prices. It is supported by the vast empirical research in the psychology literature [41,42]. It provides a behaviorally compelling alternative to exponential smoothing reference-price formation process in Equation (1), where consumers anchor on a weighted average of all prior prices.

As indicated in Nasiry and Popescu [39], the analysis of the dynamic pricing policies under the new memory-based reference-price formation process is quite difficult due to nonsmoothness in the profit function. Thus, the standard optimization techniques do not work. Nasiry and Popescu [39] develop a novel approach based on a bounding technique to characterize the optimal steady-state pricing policies. They show that a constant pricing policy is optimal for a range of relatively low initial price expectations. Unlike the exponential smoothing reference-price formation process, the optimal steady-state price depends on initial low price expectations. This result suggests that

the impact of initial low price expectations is more lasting than previously perceived in the literature. They also show that when initial price expectations of consumers are outside of the steady-state range, then firms should use price skimming or penetration strategies to gradually manage price perception, which eventually lead prices to converge to the optimal steady-state value in the long run.

The key managerial insight in Nasiry and Popescu [39] is that if a constant pricing strategy, such as EDLP, is engrained in consumer expectations, its long-term effects on prices and profits should be expected and these effects can be lessened through gradually increasing prices to manage consumer expectations.

RESEARCH GAPS AND FUTURE RESEARCH DIRECTIONS

The current studies on dynamic pricing models with reference-price effects are all deterministic and do not incorporate any uncertainty in model parameters. Thus, it would be useful to develop models that explore optimal dynamic pricing strategies when firms' knowledge on consumers' memory parameter and sensitivity to past prices are uncertain. Such study enables us to check how robust the resulting dynamic pricing policies are under information uncertainty and thus provides important insights in practice.

Consumers may learn through their purchasing experience and build their anticipations on when prices will go down and how prices will cycle over time. Such consumers may act strategically toward the dynamic pricing policies. Thus, firms should take this strategic consumer learning behavior into account in establishing their dynamic pricing policies. It would be useful to investigate what characteristics dynamic pricing policies would have when consumers learn from firms' actions, purchase strategically, and have reference-price sensitivities.

The current studies on dynamic pricing models with reference-price effects do not incorporate any capacity constraints on

firms. They all assume that firms have enough capacity to fill all consumer demand. It would be interesting to check how dynamic pricing strategies interact with capacity decisions. It is also useful to investigate whether product stock-outs have any impact on consumers' reference-price formation process. Another relevant research problem would be to build models to coordinate promotion and production decisions within a firm under the influence of reference-price effects and to investigate the value of taking reference-price effects into account in forming optimal promotion and production decisions.

The current research on dynamic pricing policies with reference-price effects focus on how consumer demand (in terms of quantity) is affected by pricing decisions. For service products, pricing strategies impact consumers' reference prices, which may impact how long consumers use the service. Thus, current studies can be extended for service products to explore how the duration of service usage by consumers is impacted by reference-price effects.

The current studies model the reference-price effects on demand through an additive function as in Equations (5)–(6). This modeling approach can be extended by considering multiplicative reference-price effects on demand.

The reference-price effect has been shown to vary across consumers [11]. This creates an opportunity for segmenting consumers based on their reference-price sensitivities. Thus, one can consider how a firm should develop dynamic pricing policies when there are several consumer segments with different reference-price sensitivities.

Current studies assume that reference-price effects for both gains and losses are independent from consumers' sensitivities to price and brand loyalty. It would be useful to develop both analytical and empirical models to assess the robustness of this assumption in developing optimal dynamic pricing and price promotion models.

DYNAMIC PROGRAMMING: INTRODUCTORY CONCEPTS

MOSHE SNIEDOVICH
Department of Mathematics and Statistics,
University of Melbourne, Melbourne,
Victoria, Australia

Dynamic programming (DP) is a general-purpose problem-solving methodology based on problem decomposition. Its origins, more accurately the origins of some of its rudimentary ideas, can no doubt be traced back to the days when humans began to *plan*. But it was the applied mathematician Richard Ernest Bellman (1920–1984), who brought together and systematized the simple, intuitive, yet highly effective ideas that underlie this problem-solving methodology, into a coherent theory [1,2]. Details on the history of DP can be found in Bellman's [3] autobiography and in Refs 4 and 5.

To set the scene, call the problem of interest, the *Target Problem*: This is the problem we seek to solve. DP approaches the solution of the *Target Problem* indirectly, by considering a family of “related problems,” called *Modified Problems*. Typically, the *Modified Problems* are generated by varying the values of some parameters of the *Target Problem*. In this framework, the *Target Problem* is equivalent to one of the *Modified Problems* associated with some given values of these parameters.

Conceptually, the family of *Modified Problems* represents the sequence of problems arising from the application of a sequence of *decisions*. That is, following the application of the first decision, the process will progress to a new *state* so that a decision must be made as to what is to be done next. This process either continues indefinitely or terminates upon reaching its *final state*.

The question is then how should the sequence of decisions be determined, given the *goals* and *constraints* stipulated by the *Target Problem*?

THE METARECIPE

Methodologically, the DP approach to problem solving can be formulated in terms of the following metarecipe:

The DP Metarecipe

1. **Define** the *Target Problem*.
2. **Embed** the *Target Problem* in a family of related *Modified Problems* using one or more features of the *Target Problem* as parameters.
3. **Derive** a *Functional equation* relating the solutions of the *Modified Problems* to one another.
4. **Solve** the functional equation.
5. **Recover** a solution for the *Target Problem* from the solution obtained for the functional equation.

The main goal of this discussion is to describe the basic concepts employed by this recipe. The focus is on the first three stages of the recipe, hence on the *modeling* aspects of DP.

THE ART OF DYNAMIC PROGRAMMING

DP's treatment of a problem, especially modeling a problem in DP style, is widely considered to be an “art” [6,7]. This, apparently, is due to the considerable dose of imagination, creativity, insight, and so on that the modeler/analyst must often inject into the formulation of a DP model and the functional equation of DP. In practice, this means that general recipes outlining in broad terms the DP approach to problem solving are of the *easier said than done* type.

The function of the above recipe is to provide a succinct description of DP's general plan of attack; more accurately, the logic driving DP's treatment of a problem. And to illustrate its working, we shall examine DP in the setting of an *optimization problem*.

The reason for limiting this discussion to optimization problems is obvious: Although the DP approach is in fact applicable to a wide variety of problem types, in the field of *operations research*, it is used primarily to model, analyze, and solve *optimization problems*. Therefore, in this discussion the focus is exclusively on this class of problems.

The specific optimization problem to be used to illustrate the modeling aspects of DP will be the following well-known combinatorial optimization problem [8].

Traveling Salesman Problem (TSP). Determine the order in which to visit a prescribed set of cities so as to minimize the total travel time. It is required that each city be visited exactly once. The trip commences and terminates at a given “home” city.

There are several mathematical formulations of this problem. For the purposes of this discussion, it is convenient to state the TSP as follows:

Target Problem for the TSP:

$$t^* := \min_{x_1, \dots, x_k} \left\{ t(h, x_1) + t(x_k, h) + \sum_{j=1}^{k-1} t(x_j, x_{j+1}) \right\} \quad \text{s.t. } \{x_1, \dots, x_k\} = \mathcal{K}, \quad (1)$$

where h denotes the home city, $\mathcal{K} := \{1, 2, \dots, k\}$ denotes the set of cities to be visited, $t(i, j)$ denotes the travel time along the (shortest) direct link from city i to city j , and x_j denotes the j th city on the tour. If there is no direct link from city i to city j , set $t(i, j) = \infty$.

Note that since $\mathcal{K} = \{1, 2, \dots, k\}$, it follows that the constraint $\{x_1, \dots, x_k\} = \mathcal{K}$ in Equation (1) requires a tour $(x_1, \dots, x_k)$ to be a *permutation* of the elements of $\mathcal{K}$. Also, observe that formally we have $x_{k+1} = h$, namely the last decision is “return to the home city.” However, since this decision is fixed in advance, we do not incorporate it explicitly in this model.

To formulate a DP functional equation for this *Target Problem*, let

$$\mathbf{S} := \{(c, C) : C \subset \mathcal{K}, c \in \mathcal{K} \setminus C\} \cup \{(h, \mathcal{K}), (h, \{\})\}, \quad (2)$$

where $\{\}$ denotes the empty set.

This set ($\mathbf{S}$) represents the *state space* of the problem. A state $s \in \mathbf{S}$ is then a pair (c, C) , where c represents the “current city,” namely, the city being visited, and C represents the set of cities yet to be visited. The *initial state* is $s = (h, \mathcal{K})$ and the *terminal state* is $s = (h, \{\})$. As the tour progresses from one city to the next, the state of the process is varied in accordance with the following *transition law*: if while at state $s = (c, C)$ the decision is to go to next city $x \in C$, then the next state of the process will be $s' = (c', C')$, where $c' = x$ and $C' = C \setminus \{x\}$.

Consider now the following family of *Modified Problems*.

Modified Problem $P(c, C)$, $(c, C) \in \mathbf{S}$:

$$f(c, C) = \min_{x_1, \dots, x_m} \left\{ t(c, x_1) + t(x_m, h) + \sum_{n=1}^{m-1} t(x_n, x_{n+1}) \right\}, m = |C| \quad (3)$$

$$\{x_1, \dots, x_m\} = C, \quad (4)$$

where $|C|$ denotes the cardinality of set C .

In this formulation, the parameter $s = (c, C)$ represents the *state* of the decision-making process, observing that for $s = (h, \mathcal{K})$, *Modified Problem $P(s)$* is equivalent to the *Target Problem*, hence $t^* = f(h, \mathcal{K})$ and any optimal solution to *Modified Problem $P(h, \mathcal{K})$* is also optimal with respect to the *Target Problem* given in Equation (1).

Note that to simplify the notation, we do not include the final decision $x_{k+1} = h$ (“return to the home city”) explicitly in this formulation. However, observe that the impact of this decision on the objective function is represented by the term $t(x_m, h)$ in Equation (3).

In words, the task set by *Modified Problem $P(c, C)$* is to find the shortest tour that commences at city c , goes through the cities in

C , and terminates at the home city h , subject to the constraint that each city in C must be visited exactly once.

From a DP point of view, *Modified Problem* $P(c, C)$ requires identifying the best sequence of decisions $(x_1, \dots, x_m)$ (with $x_{m+1} = h$) that transforms the state $s = (c, C)$ to the final state $s' = (h, \{\})$ subject to the above constraint. The term $t(x_m, h)$ in the objective function (3) represents the cost of the transition from the state $(x_m, \{\})$ to the final state $(h, \{\})$.

The DP functional equation for these *Modified Problems* is as follows:

$$f(c, C) = \min_{x \in C} \{t(c, x) + f(x, C \setminus \{x\})\}, \quad (c, C) \in \mathbf{S}, C \neq \{\}, \quad (5)$$

with $f(c, \{\}) := t(c, h)$, $\forall c \in \mathcal{K}$ (representing the transition cost from state $s = (c, \{\})$ to the final state $s' = (h, \{\})$).

The element of “art” comes into play in the DP approach when the statement of the *Target Problem* is translated into a family of *Modified Problems* for which there is a valid DP functional equation. The question of course is what kind of “instruction” can be given in this regard. Consider then Bellman’s [2, p. 82] thoughts on this matter:

We have purposely left the description a little vague, since it is the spirit of the approach that is significant rather than the letter of some rigid formulation. It is extremely important to realize that one can neither axiomatize mathematical formulation nor legislate away ingenuity. In some problems, the state variables and the transformations are forced on us; in others, there is a choice in this matters and the analytic solution stands or falls upon this choice; in still others, the state variables and sometimes the transformations must be artificially constructed. Experience alone, combined with often trial and error, will yield suitable formulations of involved processes.

One need hardly point out that this statement remains relevant to this day, not as a sign of lack of progress, but rather as testimony to the fundamental difficulties encountered in DP modeling.

BASIC CONCEPTS

Experience has shown, though, that when modeling in DP style, it is expedient to treat the *Target Problem* and its affiliated *Modified Problems* as *sequential* or *multistage* decision-making problems [2, 6, 7, 9–11]. The advantage of this approach is of course reflected already in DP’s basic idiom and in the logical progression underlying the derivation of the DP functional equation.

Sequential Decision Models

The theory of DP offers a variety of models to describe the *Target Problem*, *Modified Problems*, and the *functional equation* relating them to one another. For our purposes, however, it will be best to study a simple model, which at the same time will exhibit the main generic characteristics of DP models.

Suppose then that under consideration is a process requiring k decisions $(d_1, d_2, \dots, d_k)$, where k is a given positive integer. In this case, the *Target Problem* under consideration would be as follows:

$$\text{Target Problem: } z^* := \underset{(d_1, \dots, d_k)}{\text{opt}} g(d_1, \dots, d_k), \quad (6)$$

subject to some constraints on the decision variables $(d_1, d_2, \dots, d_k)$, and where g is a real-valued *objective function*.

From the standpoint of DP, this optimization problem is a sequential decision problem induced by a *sequential decision process*. So the fundamental modeling issue here is the following:

Suppose that the values of the first $n < k$ decision variables $(d_1, \dots, d_n)$ have already been determined (not necessarily in accordance with the optimality criterion). *What information about this partial list of decisions is required in order to find the optimal values of the remaining decisions $(d_{n+1}, \dots, d_k)$?*

The information required about $(d_1, \dots, d_n)$ for this purpose is represented by the *state variable* of a DP model, so it is defined accordingly. With this in mind, consider the sequential decision process whose basic ingredients are as follows:

Stages. There are k decision stages, $n = 1, 2, \dots, k$, at each of which a decision d_n is made. The process terminates at the final stage $n = k + 1$, where no decision is made. Let then $\mathcal{N} := \{1, 2, \dots, k\}$ denote the set of decision stages.

There are cases where the stage variable is used *implicitly*. For instance, in the case of the TSP, the state $s = (c, C)$ specifies the stage of the process implicitly, namely, $n = k + 1 - |C|$. In such cases, an explicit reference to n is not required but is often made for convenience and/or clarification.

States. At any stage, the status of the decision-making process is described by a parameter called *state*. Let $S(n)$ denote the set of feasible states at stage n . We shall refer to $S(n)$ as the *state space at stage n* . Let $\mathbf{S}$ denote the set of all the states, namely, set $\mathbf{S} = \cup_{n=1}^{k+1} S(n)$. We shall refer to $\mathbf{S}$ as the *state space*. It is assumed that the initial state of the process, namely s_1 , is given. Let σ denote the initial state, hence let $S(1) := \{\sigma\}$.

Recall that in the context of the TSP, the state of the process is a pair $s = (c, C)$, where c represents the current city and C represents the set of cities to be visited. More formally, the state space is given by Equation (2) with the state $s = (h, \{\})$ being the *terminal state*. In contrast, the state $s = (h, \mathcal{K})$ is the *initial state* associated with the *Target Problem*, meaning that the tour is at the home city ($c = h$) and that all the other cities ($C = \mathcal{K}$) are yet to be visited.

Decisions. The task is to make a sequence of decisions $(d_1, \dots, d_k)$. The decisions available at a given stage depends on the state of the process at that stage. That is, the n th decision, d_n , must be selected from a set whose content depends on the stage and state of the process when the choice is made. Let $D(n, s_n)$ denote the set of feasible decisions associated with state s_n at stage n . Hence, the requirement is that at each stage n , the decision d_n must be selected from the set $D(n, s_n)$.

In the case of the TSP, the decision made at state $s = (c, C)$ is the next city to be visited, hence $D(c, C) = C$, if $C \neq \{\}$ and $D(c, \{\}) = \{h\}$ if $C = \{\}$, recalling that C denotes the set of cities yet to be visited. Note that, as explained above, in this case the stage of

the process is not specified explicitly because its value is determined (implicitly) by the state.

State Transition. The dynamics of the process, insofar as the state is concerned, is governed by a *Markovian* transition function. That is, the next state of the process is determined by the current state and the current decision. Let T denote the (state) transition function, namely, let $T(n, s, d)$ denote the new state resulting at stage $n + 1$ from the decision d made at stage n when the process is in state s . Thus, if the initial state of the process is s_1 and the sequence of decisions $(d_1, \dots, d_k)$ is made, the resulting *state trajectory* $(s_1, s_2, \dots, s_{k+1})$ would be determined by $s_{n+1} = T(n, s_n, d_n)$, $n \in \mathcal{N}$. Note that this means that

$$S(n+1) = \{T(n, s, d) : s \in S(n), d \in D(n, s)\}, \\ n = 1, 2, \dots, k, \quad (7)$$

recalling that $S(1) = \{\sigma\}$, where σ denotes the initial state of the process.

In the case of the TSP, $T((c, C), d) = (d, C \setminus \{d\})$, $d \in D(c, C)$, observing once again that there is no explicit reference to the stage variable.

Objective Function. The decisions are made for the purpose of optimizing some given real-valued function of the decision and state variables, call it g . For simplicity, assume that the objective function is *additive* in that it has the following additive structure.

$$g(s_1, d_1, d_2, \dots, d_k) = \sum_{n=1}^k r(n, s_n, d_n), \quad (8)$$

where r is a real-valued function of (stage, state, decision) triplets. We refer to $r(n, s, d)$ as the *stage return* induced by the (stage, state, decision) triplet (n, s, d) .

In the case of the TSP, $r((c, C), d) = t(c, d)$, namely, the stage return $r((c, C), d)$ represents the travel time from city c to city d along the direct link between these cities.

In the next section, we examine how this model is used to define the *Modified Problems* related to the *Target Problem*.

Modified Problems

To obtain the *Modified Problems* associated with the above model, the values of initial segments of the complete sequence of decisions $(d_1, \dots, d_k)$ are fixed. Those problems that are *equivalent* with regard to the optimal values of the remaining decision variables are then aggregated in the *state* variable. The difference between the *Modified Problems* lies in the choice of the (stage, state) pair. So, in this framework, the *Target Problem* is simply one of the *Modified Problems* associated with a given (stage, state) pair, namely, $(n, s) = (1, \sigma)$, recalling that σ denotes the initial state of the process.

The following formulation captures this intuitive idea and provides a convenient mathematical framework for an examination of the basic concepts of DP.

Modified Problem $P(n, s), n \in \mathcal{N}, s \in S(n)$:

$$f_n(s) := \text{opt}_{d_n, \dots, d_k} \left\{ \sum_{j=n}^k r(j, s_j, d_j) \right\} \quad (9)$$

$$s_n = s \quad (10)$$

$$d_j \in D(j, s_j), j = n, n+1, \dots, k \quad (11)$$

$$s_{j+1} = T(j, s_j, d_j), j = n, n+1, \dots, k. \quad (12)$$

By definition then, $f_n(s)$ denotes the optimal value of the objective function given that the initial stage of the process is $n \in \mathcal{N}$ and the initial state of the process is $s \in S(n)$. The sum of the stage returns is often called the *cost-to-go*. These problems are defined so that the *Target Problem* is equivalent to *Modified Problem* $P(1, \sigma)$.

Let $X^*(n, s)$ denote the set of optimal solutions to *Modified Problem* $P(n, s)$, $n \in \mathcal{N}, s \in S(n)$. Assume that every *Modified Problems* has at least one optimal solution.

We are now ready to sketch out the logical process yielding the DP functional equation for the *Modified Problems* defined above. But before we do this, it is important to point out that the simplicity of the concepts underlying the derivation of the DP functional equation in no way casts doubts on the ability of those concepts to vouchsafe the validity of the equation. Indeed, Bellman himself was aware that such doubts might be raised.

And so, interrupting the discussion in which the derivation of the functional equation was demonstrated for the first time in the book, Bellman suggested the following [[2], p. 8]:

This observation, simple as it is, is the key to all our subsequent mathematical analysis. It is worthwhile for the reader to pause here a moment and make sure that he really agrees with this observation which has the deceptive simplicity of a half-truth.

It is important to keep this suggestion in mind!

Conditional Problems

The notion *Conditional Problems* represents a “what if” ploy aimed at solving the *Modified Problems* surreptitiously. That is, in lieu of asking bluntly the obvious question “what is the optimal value of d_n for *Modified Problem* $P(n, s)$?” which may be rather difficult to work out, we ask the following naive question: “What if we set the value of d_n to some arbitrary element d of $D(n, s)$?” More precisely, “What is the best result that can be obtained in the context of *Modified Problem* $P(n, s)$ if the value of d_n is fixed to some arbitrary $d \in D(n, s)$?”

It turns out that the answer to this question is easily obtainable if we are “allowed” to express the optimal solution to *Modified Problem* $P(n, s)$ in terms of the optimal solutions to modified problems associated with stage $n+1$. Indeed, this takes us closer to formulating the DP functional equation. In short, to obtain the family of *Conditional Problems* associated with the above family of *Modified Problems*, we simply fix the value of decision d_n to some arbitrary value $d \in D(n, s)$. Hence,

Conditional Problem $P(n, s, d), n \in \mathcal{N}, s \in$

$S(n), d \in D(n, s)$:

$$f_n(s, d) := \text{opt}_{d_n, \dots, d_k} \left\{ \sum_{j=n}^k r(j, s_j, d_j) \right\} = r(n, s, d) + \text{opt}_{d_{n+1}, \dots, d_k} \left\{ \sum_{j=n+1}^k r(j, s_j, d_j) \right\} \quad (13)$$

$$s_n = s \quad (14)$$

$$d_n = d \quad (15)$$

$$d_j \in D(j, s_j), \quad j = n+1, \dots, k \quad (16)$$

$$s_{j+1} = T(j, s_j, d_j), \quad j = n, \dots, k. \quad (17)$$

Let $X^*(n, s, d)$ denote the set of optimal solutions to *Conditional Problem* $P(n, s, d)$. Assume that every *Conditional Problem* has at least one optimal solution. Observe that by definition, $f_k(s, d) = r(k, s, d)$, $\forall s \in S(k)$, $d \in D(k, s)$.

Principle of Conditional Optimization

By definition, the only difference between *Modified Problem* $P(n, s)$ and *Conditional Problem* $P(n, s, d)$ is that in the former d_n represents a *decision variable* to be selected from $D(n, s)$, whereas in the latter the value of d_n is set to some *arbitrary value* $d \in D(n, s)$. It follows then that

$$f_n(s) = f_n(s, d), \text{ for some } d \in D(n, s), \quad (18)$$

for all $n \in \mathcal{N}$, $s \in S(n)$. Hence,

Theorem 1 [Principle of Conditional Optimization, 7].

$$f_n(s) = \underset{d \in D(n, s)}{\text{opt}} f_n(s, d) \quad \forall n \in \mathcal{N}, s \in S(n). \quad (19)$$

The significance of this obvious result is that it enables linking *Modified Problem* $P(n, s)$ to *Modified Problem* $P(n+1, T(n, s, d))$ via *Conditional Problem* $P(n, s, d)$. As suggested by the *metarecipe*, this link is the DP functional equation.

Principle of Optimality

This principle was formulated by Bellman [2, p. 83] as follows:

Principle of Optimality. An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision.

In the context of our analysis, it can be stated formally as follows:

Theorem 2 [Principle of Optimality]. For any triplet (n, s, d) such that $1 \leq n < k$, $s \in S(n)$, $d \in D(n, s)$, the set of optimal solutions to *Conditional Problem* $P(n, s, d)$ is equal to the set of optimal solutions to *Modified Problem* $P(n+1, T(n, s, d))$. That is,

$$X^*(n, s, d) = X^*(n+1, T(n, s, d)), \quad \forall 1 \leq n < k, \\ s \in S(n), d \in D(n, s). \quad (20)$$

The *Principle of Optimality* asserts that any optimal solution to *conditional problem* at (n, s, d) is also optimal for the *Modified Problems* that it generates, namely, *Modified Problem* $P(n+1, T(n, s, d))$, and vice versa. Thus, insofar as the optimal values of the (remaining) decision variables $(d_{n+1}, \dots, d_k)$ are concerned, *Conditional Problem* $P(n, s, d)$ is equivalent to the *Modified Problem* $P(n+1, T(n, s, d))$.

The following is a direct implication of the *Principle of Optimality*.

Theorem 3 [7].

$$f_n(s, d) = r(n, s, d) + f_{n+1}(T(n, s, d)), \\ \forall 1 \leq n < k, s \in S(n), d \in D(n, s). \quad (21)$$

The question is then, what is the best choice for d given (n, s) ? That is, what is the best choice for decision d if we are at stage n observing state s ? The answer is obvious: the best value of d is one that optimizes the right-hand side of Equation (21).

Functional Equation

The following is a direct implication of Theorem 1 and 3.

Theorem 4 [DP Functional Equation, 7].

$$f_n(s) = \underset{d \in D(n, s)}{\text{opt}} \{r(n, s, d) + f_{n+1}(T(n, s, d))\}, \\ \forall n \in \mathcal{N}, s \in S(n), \quad (22)$$

with $f_{k+1}(s) := 0$, $\forall s \in S(k+1)$.

It should be emphasized that Equation (22) is not a definition of $f_n(s)$. That is, $f_n(s)$ is defined in Equation (9). Rather, Theorem 4 spells out an important property of the functions $(f_n : n = 1, 2, \dots, k)$ defined in Equation (9).

Terms such as *functional equation*, *Bellman equation*, *optimality equation*, and *recurrence relation* are used to describe the relation stipulated by Theorem 4.

Policies

In the framework of DP, a *policy* is a *rule* governing the choice of decisions [2,7,11]. DP offers a number of such rules, but of special interest is the rule governing the choice of a decision which depends on the *stage and state* of the process. We refer to such policies as *Markovian policies*. So, in the context of the DP model described in the preceding section, a *Markovian policy* is a rule δ that assigns to each (stage, state) pair (n, s) a feasible decision $d \in D(n, s)$.

An application of a Markovian policy δ to a state s at stage n yields a state trajectory $(s_n, \dots, s_{k+1})$ and a sequence of decisions $(d_n, \dots, d_k)$ such that $s_n = s$, $d_j = \delta(j, s_j)$, and $s_{j+1} = T(j, s_j, d_j)$, $j = n, \dots, k$.

A *DP policy* is a Markovian policy that is a solution to the DP functional equation. In other words, a DP policy is a Markovian policy δ^* such that

$$\delta^*(n, s) \in D^*(n, s), \forall n \in \mathcal{N}, s \in S(n), \quad (23)$$

where $D^*(n, s)$ denotes the set of all the optimal solutions to the functional equation at (n, s) , namely,

$$D^*(n, s) := \{d^* \in D(n, s) : f_n(s, d^*) = f_n(s)\}, \quad n \in \mathcal{N}, s \in S(n), \quad (24)$$

recalling that $f_n(s, d) = r(n, s, d) + f_{n+1}(T(n, s, d))$.

All the DP policies are simultaneously optimum for all the *Modified Problems*, including the one corresponding to the *Target Problem*.

Solution Methods

There is no general-purpose recipe for the solution of DP functional equations. Still, it is possible to distinguish between two approaches that can be outlined broadly as follows:

Direct Methods [2,7,11]. These methods basically determine the value of $f_n(s)$ for each $n \in \mathcal{N}$ and $s \in S(n)$ by evaluating the right-hand side of the DP functional equation. In particular, if there are finitely many stages and states, the following procedure suggests itself.

Initialization: Set $n \leftarrow k + 1$ and $F_{k+1}(s) \leftarrow 0$, $\forall s \in S(k + 1)$.

Stage Iteration: For $n = k, k - 1, \dots, 1$ Do:

State Iteration: for $s \in S(n)$ Do:

$$F_n(s) \leftarrow \text{opt}_{d \in D(n, s)} \{r(n, s, d) + F_{n+1}(T(n, s, d))\} \quad (25)$$

End Do

End Do

There is likewise no “general-purpose” method for solving the optimization problem specified by the right-hand side of Equation (25). The method used is contingent on the structure of the objects involved.

If this optimization problem is solved by enumerating $d \in D(n, s)$, then in addition to the “stage loop” and the “state loop,” there is also an inner “decision loop.” Upon completion, we obtain $F_n(s) = f_n(s)$, $\forall n \in \mathcal{N}, s \in S(n)$.

Successive Approximation Methods [2,7,11]. These are iterative procedures that begin with an initial approximation of either f or a DP policy, and improve on it successively. That is, using the current approximation, the DP functional equation is solved for this approximation, to obtain a new approximation and so on. The procedure terminates when no further improvement is possible.

For instance, consider the following “stage-less” DP functional equation.

$$f(s) = \text{opt}_{d \in D(s)} \{r(s, d) + f(T(s, d))\}, s \in \mathbf{S}, \quad (26)$$

where function f is defined on $\mathbf{S}$ by a DP sequential decision model.

If the initial approximation of the unknown function f is set to $f^{(a)}$, then a basic successive approximation scheme would be as follows:

Initialization: For each $s \in \mathbf{S}$ set $F(s) \leftarrow f^{(a)}(s)$.

Iteration: For each $s \in \mathbf{S}$ set

$$F(s) \leftarrow \text{opt}_{d \in D(s)} \{r(s, d) + F(T(s, d))\} \quad (27)$$

Termination: Stop if there is no improvement in F .
Otherwise continue with the iteration.

An important factor in successive approximation schemes of this type is the order in which the states are enumerated in each iteration. And of course, certain technical “regularity” conditions must hold so as to guarantee the convergence of such successive approximation schemes and to ensure that the solutions obtained by the scheme is the function f defined by the DP model.

One of the most celebrated algorithms in computer science, namely, *Dijkstra’s Algorithm* for the shortest path problem, is a typical DP successive approximation method, albeit not as simple as the basic one outlined above [11,12].

COMPLETE ENUMERATION

One of the stories about Bellman’s work on DP is that one of his early papers was rejected from publication on the grounds that the proposed procedure (for the solution of the DP functional equation) was deemed a *complete enumeration* procedure in disguise. Indeed, this is how this procedure can appear to newcomers to the field.

It is important to stress, therefore, that except for some pathological cases, the solution of the DP functional equation clearly does not amount to a complete enumeration. The factor that is instrumental in “saving” the procedure from this “ignominy” is the *state variable*.

For example, consider the TSP. Recall that in this context a state is a pair $s = (c, C)$,

where c is a city and C is a set of cities. The fact that C represents all the subtours (partial solutions) consisting of $m = |C|$ cities selected from C (without replacement) means that typically a single state $s = (c, C)$ represents many subtours. Hence, the task of enumerating the states of a TSP is much less demanding than the task of enumerating all the subtours associated with the problem.

To illustrate, consider the case where $c = 3$ and $C = \{1, 2, 4, 7, 8, 9\}$. Since C consists of 6 cities, it represents $6! = 720$ partial solutions, namely permutations of the elements of C . This means that the “saving” is substantial, especially in large problems. Note that a TSP consisting of k cities has $k!$ feasible tours, whereas the state space of the DP model has less than $k2^{k+1}$ states, hence if k is large then, $k!$ is much larger than $k2^{k+1}$.

The trouble is, however, that for all its manifest superiority over complete enumeration in the solution of combinatorial optimization problems, there are many cases where the state space of the DP model grows very fast (e.g., exponentially) with the size of the problem—a point leading directly to our next topic.

THE CURSE OF DIMENSIONALITY

This graphic phrase was coined by Bellman [2, p. xii] to describe the difficulty hindering the solution of problems, whose complexity grows inordinately fast (e.g., exponentially) with their “size.”

There are many cases where the DP solution procedure is not affected by this “curse.” But there are many others where, for all the progress in DP, in computing, and so on, the “curse” presents as onerous a problem as it did in the early days of DP.

The fast (e.g., exponential) growth in the complexity of a problem with its “size” often means an inordinate growth in the *state space* of the DP model. Therefore the size of the *state space*, $\mathbf{S}$, is often a good indication of the complexity of DP algorithms.

For example, as pointed out above, in the case of the TSP, a problem of size k requires a state space consisting of more than 2^k states [8]. The situation is similar in many *scheduling problems* where the solution space

consists of *permutations* of a list of elements (jobs, projects) that grows linearly with the size of the problem [7]. Note that in these cases, there are $n!$ feasible solutions. The implication is then that the DP approach is obviously incomparably “more efficient” than *complete enumeration*. But, the fact remains that the DP functional equation would still be prohibitive, if the problem is large.

In short, the sad reality is that in many cases, it is impossible to obtain exact solutions to the DP functional equation due to the computational resources required for this purpose.

Given this state-of-affairs, for many years now the development of effective “heuristic” methods has been the subject of intensive research in DP. The appeal of such heuristic methods is that they are fast and can handle large problems. The price tag attached, though, is that such algorithms do not guarantee optimal solutions for the *Target Problem*. Worse, often such methods do not even provide an indication as to how “good/bad” the solutions they generate are in relation to the exact optimal solutions.

The fundamental difficulties encountered in providing such bounds attest to the insurmountable difficulties presented by the *curse of dimensionality*. So, despite the tremendous progress that has been made in this area over the past fifty years, the *curse of dimensionality* remains unbeatable, a fact that, needless to say, provides grist to the mills of ongoing research into the methods, which aimed at coping with it [13–16].

PERSPECTIVE

The basic concepts examined in the preceding sections can be modified so as to enable the adaptations of the DP model and functional equation discussed above to a variety of more/less complex problems. In this section, we examine briefly a number of such modifications and other aspects of DP.

Generalizations

Nonadditive Objective Functions. The objective function of a DP model need not necessarily be *additive*. While the additive form

is no doubt the most prevalent by far, other objective functions can be easily handled by DP. For instance, consider the case where the objective function has the following generic form:

$$g(s_1, d_1, d_2, \dots, d_k) = r(1, s_1, d_1) \oplus r(2, s_2, d_2) \\ \oplus \dots \oplus r(k, s_k, d_k), \quad (28)$$

where $\oplus$ is an associative binary operator [7,17].

If $\oplus$ is nondecreasing with its right argument, then the *Principle of Optimality* holds, and the DP functional equation takes the familiar form

$$f_n(s) = \underset{d \in D(n,s)}{\text{opt}} \{r(n, s, d) \oplus f_{n+1}(T(n, s, d))\}, \\ \forall n \in \mathcal{N}, s \in S(n), \quad (29)$$

with $f_{k+1}(s) = R_{\oplus}, \forall s \in S(k+1)$, where $R_{\oplus}$ denotes the (right) *identity element* of $\oplus$, namely $a \oplus R_{\oplus} = a, \forall a$ [7,17].

Some of the nonadditive forms of $\oplus$ that are used in DP models are the *multiplicative form* ($\oplus = \times$), the binary *max form* ($a \oplus b = \max\{a, b\}$), the binary *min form* ($a \oplus b = \min\{a, b\}$), and the *right-identity form* ($a \oplus b = b$). The latter plays an important role in Bellman’s conception of DP [7]. Note that the multiplicative form requires the returns to be nonnegative.

It is important to note that if $a \oplus b$ is not increasing with b , then the functional equation (Eq. 29) may not be valid, in which case it may be necessary to expand the state space and modify the DP model [7].

Infinite-Horizon Models. DP models can have infinitely (countably) many decision stages ($k = \infty$). Such models are called *infinite-horizon models*, or *nontruncated models*. Often, such models require some sort of a *discounting* feature to ensure that the total return is bounded. Furthermore, some regularity conditions must hold to guarantee that the total returns induced by Markovian policies are well defined [2,7,17].

Stochastic Models. DP models can be modified to enable the treatment of *stochastic* decision processes where the next state of

the process depends on the current state, the current decision, and some probabilistic events [2,18,19]. This gives rise to *Markovian decision processes*.

From a DP perspective, such models are characterized by the property that the application of a decision at a given (stage, state) pair can generate more than one state. That is, $T(n, s, d)$ is not an element of $S(n+1)$, it is a *subset* of $S(n+1)$. As a result, each time a decision is made a number of diverging subprocesses are initiated. The objective is often to optimize the *expected value* of the total return/cost.

Nonserial Models. These are generalizations of stochastic models in the sense that they consists of a number of subprocesses that interact with one another in a variety of ways such as diverge (as in the case of stochastic processes), converge, feedbackward, and feed-forward [9,17,20,21].

Multiobjective Models. The objective function of a DP model need not necessarily be a real-valued function [22–24]. Thus, it can be a function taking values in $\mathbb{R}^m$, representing m objectives. In this case, the DP functional equation can be used to generate the *pareto* optimal solutions to the *Target Problem*.

Forward Decomposition. The *Modified Problems* defined by Equations (9)–(12) are based on objective functions that represent the remaining part of the decision-making process, that is the “cost-to-go.” Hence, by definition $f_n(s)$ represents the optimal return generated from stage n to the final decision stage, namely stage k . Such decomposition schemes are called *backward* decomposition schemes.

There are cases where it is advantageous to use *forward* decomposition schemes [6,11]. In this framework, *Modified Problem* $P(n, s)$ poses the question: what is the best way of reaching state s at stage n from a given initial state σ at stage 1? The *Target Problem* is equivalent to *Modified Problems* $P(k+1, s)$ for some given final state $s \in S(k+1)$.

The following is the *forward* counterpart of the *backward* DP functional equation given in Equation (22).

$$f_{n+1}(s') = \underset{\substack{s \in S(n) \\ d \in D(n,s) \\ s' = T(n,s,d)}}{\text{opt}} \{f_n(s) + r(n, s, d)\},$$

$$n \in \mathcal{N}, s' \in S(n+1), \quad (30)$$

with $f_1(\sigma) = 0$, where $f_{n+1}(s')$ denotes the optimal return of reaching state s' at stage $n+1$ from the initial state σ at stage 1.

There are of course other generalizations of the DP model outlined above. For instance, the above model can be modified so as to serve as a medium for solving problems that are not “genuine” optimization problems [7] (e.g., constraint satisfaction problems), or problems where some of the sets are fuzzy [25].

Software

As pointed out already, one of the peculiarities of DP is the lack of truly “general-purpose” DP software packages for the modeling, analysis, and solution of DP functional equations. This fact is a direct implication of the rather “abstract” methodological framework put forward by DP.

There are, of course, software packages for special applications of DP and for educational purposes. More on this important aspect of DP can be found in Refs 26–29.

SUMMARY

DP is a general, wide-ranging approach to problem solving which employs the idea of *problem decomposition* as a basic ploy. Traditionally, DP has been cast as a framework expressing a *sequential decision-making process* where the *state variable* is used to aggregate equivalent subproblems into a family of *Modified Problems*. The relationship between the optimal solution to these *Modified Problems* is described by a *functional equation* whose solution provides a *policy* that is optimal with respect to all the *Modified Problems*, including the one representing the *Target Problem*.

Numerous methods are available for the solution of DP functional equations. Nevertheless, there are cases where the equation eludes solution or is subject to the *curse of dimensionality*. The relentless effort to tackle

the computational aspects of DP—including the development of user-friendly, general-purpose DP software—continues.

DYNAMIC PROGRAMMING VIA LINEAR PROGRAMMING

İSMET ESRA BÜYÜKTAHTAKIN
Systems and Industrial Engineering,
University of Arizona, Tucson,
Arizona

RELATED LITERATURE

A wide variety of problems have been shown to be polynomially solvable via dynamic programming (DP) recursive formulations. The problem is attacked by decomposing it into a sequence of interrelated subproblems defined by a recursive function and starting to solve the smallest subproblem. The problem is then enlarged by finding the current optimal solution from the preceding subproblem until the original problem is solved in its entirety. The main strength of this approach is to offer treatments to different type of problems involving sequential decision making with discrete, nonlinear, and stochastic characteristics.

DP was introduced to solve Markov decision processes by Bellman [1]. The basics of a dynamic program can be described as follows: consider a system being observed over a finite or infinite time horizon divided into periods or stages. At each stage, a decision or an action updates the state to be observed at the next stage, and depending on the state and the decision made, an immediate reward (cost) is observed. The value function represents the expected total reward (cost) from the current stage through the end of the planning horizon, while the functional equation expresses the relationship between the value function at the present stage and the successive stage. Optimal decisions depending on stage and state are determined backwards, iteratively, by maximizing (minimizing) the right-hand side of the functional equation.

The use of linear programming (LP) to solve DP formulations was first introduced by

D'epenoux [2] and Manne [3]. Manne [3] studied an undiscounted Markov decision model with an infinite planning horizon. He specifically analyzed an inventory control problem where the “state” variable represents the initial stock level i and the “decision variable” corresponds to the order quantity j . In the linear program in Manne [3], i and j are introduced as subscripts to the variables x_{ij} . These variables x_{ij} represent the joint probabilities with which the initial stock equals i and the production quantity equals j . The steady-state probabilities of inventory, production, and shortage levels are then derived. The constraints of the LP are the requirements regarding steady-state probabilities, and the objective function is the minimization of the expected cost corresponding to the steady-state probabilities. D'epenoux [2] provided a linear program for the discounted version of the problem in Manne [3] by linearizing the functional equations of the corresponding dynamic program.

Howard [4] combined DP with Markov chain theory to develop Markov decision processes. He also contributed to the solution of infinite horizon problems by developing the policy iteration method as an alternative to the backward induction method of Bellman [1], which is known as *value iteration*. The policy iteration algorithm generates a sequence of stationary policies by evaluating and improving the policies until the optimal policy is obtained. Later, Osaki and Mine [5] formulated a semi-Markovian decision process as an LP and showed that the dual of this LP is equivalent to DP formulation of Howard [4].

Another group of DP and Markov decision processes research arises from the observation that finding the optimal cost function can be cast as a LP problem [3,6–11]. However, the resulting linear program suffers from the curse of dimensionality: as the problem size linearly increases, the size of the state space grows exponentially. This LP has as many decision variables as states in the Markov decision processes, and an

even greater number of constraints. This difficulty is addressed by approximate dynamic programming (ADP), where the DP optimal cost-to-go function of the problem is approximated within the span of some prespecified set of basis functions as introduced by Schweitzer and Seidmann [12]. de Farias and Van Roy analyzed and further developed this approach by proposing the procedure known as *approximate linear programming* (ALP), which reduces the dimensionality of the linear program by utilizing a linear combination of basis functions combined with sampling only a small subset of the constraints [13–15]. de Farias and Van Roy [14] also established strong approximation guarantees for ALP-based approximations assuming knowledge of a “Lyapunov”-like function that must be included in the basis. An extension to the ALP approach that automatically generates the basis functions in the linear framework was developed by Valenti *et al.* [16]. Later, Desai *et al.* [17] studied the ADP via a smoothed linear program and developed an error bound that characterizes the quality of approximations produced by ADP.

Eppen and Martin [18] and Martin *et al.* [19] studied the underlying DP network structure to reformulate difficult integer programs into new models that have better bounds and solve them more quickly. Eppen and Martin [18] provided tighter mixed integer programming formulations for the single and multi-item lot-sizing problems using a variable redefinition approach. They first removed the capacity constraints from the traditional lot-sizing formulation and represented the subproblem with the DP network structure. This shortest path network can be written as an integer linear program (IP), with the arcs corresponding to binary variables and the nodes corresponding to flow balance constraints. Eppen and Martin then related the variables of the traditional model to the new set of variables through a linear transformation. By using this transformation, they inserted the complicating constraints in terms of the new variables into the new formulation. Although this new reformulation had a greater number of variables and constraints, it had a tighter LP relaxation lower bound leading to reduced

solution times. Martin *et al.* [19] formulated polynomially solvable optimization problems as shortest path problems by using DP. They then represented the dynamic program as an LP having a polynomial number of variables and constraints. The extreme points of this LP are represented by the solution vectors of the DP, and the dual of the LP provides the DP formulation. They also showed that with an appropriate change of variables, the LP formulation obtained from the DP provides a polyhedral description of the model considered.

There are a number of studies that utilize DP algorithms to formalize and solve integer linear programming problems [20–25]. In a recent study, Hartman *et al.* [26] introduced a set of DP-based inequalities that can be used to augment the capacitated lot-sizing integer linear programming (CLSP) formulation. These authors utilized iterative solutions of forward DP formulations for CLSP to generate inequalities for an equivalent integer programming formulation. The inequalities capture convex and concave envelopes of intermediate-stage value functions, and can be lifted by examining potential state information at future stages. Lawler and Wood [27] discussed the close relationship between branch and bound and DP, while Morin and Marsten [28] studied branch and bound techniques to reduce storage and computational requirements in discrete DP. In particular, they utilized relaxations and fathoming criteria in branch and bound to eliminate states of DP, which will not lead to optimal policies.

The article is outlined as follows. In the second section, we review the close relationship between LP techniques and DP in stochastic control, while we discuss the utilization of DP driven acyclic decision graphs to describe polyhedral characteristics of discrete optimization problems in the third section. The fourth section concludes the article and offers directions for future research.

LP-DP RELATIONSHIP IN STOCHASTIC CONTROL

In this section, we consider a discrete-time stochastic control problem involving a finite

state space $S = (1, \dots, n)$. Let $\mathcal{U}$ be a finite decision set for all $i \in S$. Given state i , the use of decision $u \in \mathcal{U}$ specifies the transition probability $p_{ij}(u)$ to the next stage j , and a cost $g(i, u)$ is incurred when a decision u is taken in state i . Future costs are discounted by a factor $\alpha \in (0, 1)$. A policy of the stochastic control problem is denoted by $\mu : S \rightarrow \mathcal{U}$. The problem is then to minimize the so-called cost-to-go function $J_\mu : S \rightarrow \mathcal{U}$ over the set of admissible policies $\mathcal{P}$:

$$\min_{\mu \in \mathcal{P}} J_\mu(i_0) = \min_{\mu \in \mathcal{P}} \mathbb{E} \left[\sum_{k=0}^{\infty} \alpha^k g(i_k, \mu(i_k)) \right], \quad (1)$$

where $i_0 \in S$ is an initial state and the expectation $\mathbb{E}$ is taken over the possible future states $\{i_1, i_2, \dots\}$, given i_0 and the policy μ .

The optimal cost associated with the optimal policy μ^* , denoted by $J^* = J_{\mu^*}$, satisfies the Bellman equation:

$$J(i) = \min_{u \in \mathcal{U}} \left[g(i, u) + \alpha \sum_{j \in S} p_{ij}(u) J(j) \right], \quad \forall i \in S, \quad (2)$$

which is called value iteration and is a principal method for calculating the optimal cost function J^* [7]. Once J^* is found by solving Equation (2), the optimal policy μ^* can be computed.

An alternative approach to solving the stochastic control problem described here is to fix the policy μ and then solve the following linear system:

$$J_\mu(i) = g(i, \mu(i)) + \alpha \sum_{j \in S} p_{ij}(\mu(i)) J_\mu(j), \quad \forall i \in S. \quad (3)$$

Solving Equation (3) is called as *policy evaluation* yielding J_μ , the cost-to-go of the fixed policy μ . After computing the policy's cost-to-go function, a better policy can be constructed by performing a policy improvement step. The policy iteration method repeatedly performs policy evaluation followed by policy improvement. This procedure generates a sequence of policies that is guaranteed to converge to the optimal policy μ^* after a

finite number of iterations since the new policy must be strictly better than the previous policy and there is only a finite number of possible policies in total [4].

LP Formulation of DP

Suppose that we use value iteration to generate a sequence of vectors $J_k = (J_k(1), \dots, J_k(n))$ given an initial condition vector $J_0 = (J_0(1), \dots, J_0(n))$. Then the following constraints

$$J(i) \leq g(i, u) + \alpha \sum_{j \in S} p_{ij}(u) J(j), \quad \forall i \in S, u \in \mathcal{U}, \quad (4)$$

form a polyhedron in R^n . The optimal cost vector $J^* = (J^*(1), \dots, J^*(n))$ solves the following problem (in $w_1, \dots, w_n$)

LP1:

$$\max \sum_{i \in S} w_i \quad (5)$$

$$\text{subject to } w_i \leq g(i, u) + \alpha \sum_{j \in S} p_{ij}(u) w_j, \quad \forall i \in S, u \in \mathcal{U}. \quad (6)$$

This is a linear program with n variables and as many as $n \times q$ constraints, where q is the maximum number of elements of the set $\mathcal{U}$. For very large n and q , the linear program can be solved by the use of specialized, large-scale LP algorithms [7, 11].

Dual and Policy Iteration

We now investigate the dual of **LP1** which is shown to be the same as policy iteration [9]. Duality theory of LP [29] asserts that the following dual linear program:

Dual1:

$$\min \sum_{i \in S} \sum_{u \in \mathcal{U}} q(i, u) g(i, u) \quad (7)$$

$$\text{subject to: } \sum_{u \in \mathcal{U}} q(i, u) - \alpha \sum_{j \in S} \sum_{u \in \mathcal{U}} q(j, u) p_{ji}(u) = 1, \quad \forall i \in S, \quad (8)$$

$$q(i, u) \geq 0, \quad \forall i \in S, u \in \mathcal{U}, \quad (9)$$

has the same optimal value as **LP1**. The variables $q(i, u)$, $i \in S$, $u \in \mathcal{U}$, of the dual program can be interpreted as the steady-state probabilities that state i will be visited at the typical transition and control u will then be applied. The constraints of **Dual1** are the constraints that $q(i, u)$ must satisfy in order to be feasible steady-state probabilities. The cost function

$$\sum_{i \in S} \sum_{u \in \mathcal{U}} q(i, u) g(i, u)$$

is the steady-state average cost per transition.

Denardo [9] shows that the feasible bases for **Dual1** are in one-to-one correspondence with the policies. Denardo also proves that the application of the simplex method to the dual program performs the same sequence of pivots as does policy iteration and policy iteration is the same as multiple substitution (block pivoting) in the dual simplex method, as applied to **LP1**.

LP-DP RELATIONSHIP THROUGH ACYCLIC GRAPHS

Many discrete optimization problems that are solvable through DP can be represented by directed acyclic shortest path decision graphs [9,22,30,31]. Given a finite state set S , vertices of the graph correspond to states of S reflecting the transition phases in the solution of the underlying sequential decision process. Arcs (i, j) between vertices $i, j \in S$ represent decisions changing the state i to state $j > i$. Furthermore, each arc is assigned a cost equal to the length of the arc. The problem is then to find the shortest path from an initial state to a goal state. Generally, states are partitioned into stages such that the decision at a stage updates the state at the stage into the state for the next stage.

Once the shortest path formulation of a discrete optimization problem is constructed, the shortest path problem can easily be written as a linear program where variables represent arcs and the flow balance at each vertex is expressed as a constraint. This LP provides the polyhedral characterization of the discrete optimization problem where

every face of the associated polytope contains the incidence vector of a decision path in the DP graph. For any given cost function, one such incidence vector will be the LP optimal solution [19].

One problem with the acyclic shortest path paradigm is that it is inadequate for more complex discrete optimization problems since a typical decision involves composing two or more partial solution elements into a single element. To overcome this difficulty, Martin *et al.* [19] developed a directed acyclic decision hypergraph framework for deriving extended formulations of combinatorial optimization problems from DP algorithms as mentioned in the section titled "Related Literature". The DP algorithms considered in Martin *et al.* [19] search hyperpaths in a directed hypergraph $\mathcal{H} = (S, H)$ on a finite state space S with cardinality $|S| = n$, where the directed hyperarcs in $\mathcal{H}$ are of the form (K, j) with $j \in S$ and $K \subseteq S$. The states are ordered by a numbering function $\sigma : S \rightarrow \{1, 2, \dots, m \triangleq |S|\}$ such that $\sigma(i) < \sigma(j)$ for all $(K, j) \in H$ and $i \in K$. Furthermore, it is assumed that the directed hypergraph is single tailed. The set $S_T \subset S$ of boundary states is the set of all $j \in S$, for which there is a hyperarc $(\emptyset, j) \in H$ and all nonboundary states are called as *intermediate*. Finally, there must be a finite reference set $I(j) \neq \emptyset$ for each state $j \in S$ such that $I(i) \subseteq I(j)$ and $I(i) \cap I(i') = \emptyset$, for all $i, i' \in K$, where $i \neq i'$ is satisfied for all $(K, j) \in H$.

In this setting, Martin *et al.* [19] proved the convex hull of the characteristic vectors of decision paths in the DP hypergraph is described by the following linear program

$$\text{LP2:} \quad \min \sum_{(K,j) \in H} c[K, j] z[K, j] \quad (10)$$

$$\text{subject to:} \quad \sum_{(K,m) \in H} z[K, m] = 1, \quad (11)$$

$$\sum_{(K,\bar{j}) \in H} z[K, \bar{j}] - \sum_{(K,j) \in H \text{ with } \bar{j} \in K} z[K, j] = 0$$

$$\text{for } \sigma(\bar{j}) = 1, \dots, m-1, \quad (12)$$

$$z[K, j] \geq 0 \quad \forall (K, j) \in H, \quad (13)$$

where $z[K, j]$ is a binary (0 – 1) variable that takes value 1 if the hyperarc (K, j) is selected, and 0 otherwise, and $c[K, j]$ represents the cost of selecting the hyperarc (K, j) . The objective function (10) minimizes the cost of choosing a particular path, while constraint (11) ensures that exactly one decision will terminate at the global state m . Constraint (12) enforces flow balance conditions. Constraints (11) and (12) with the nonnegativity constraints (13) are shown to be sufficient to produce a binary solution to the primal linear program **LP2**.

LP2 can be viewed as the dual to the computations of the dynamic program itself. Thus, we provide the dual of the problem above as follows:

Dual2:

$$\max \omega \quad (14)$$

$$\text{subject to: } \omega - \sum_{i \in K} \lambda[i] \leq c[K, m],$$

$$\forall (K, m) \in H, \quad (15)$$

$$\lambda[j] - \sum_{i \in K} \lambda[i] \leq c[K, j],$$

$$\forall (K, j) \in H; j \neq m. \quad (16)$$

Here ω denotes the dual multiplier for constraint (11), and $\lambda[j]$ is the dual variable for row $\sigma(\bar{j})$ of Equation (12). Note that **Dual2** is equivalent to the DP formulation.

CONCLUSIONS AND FUTURE REMARKS

In this article we survey LP approaches for solving DP formulations of hard optimization problems. In particular, we analyze techniques used for casting a dynamic program as a linear program. An LP with few variables and a large number of constraints is often tractable via large-scale LP algorithms such as constraint generation. However, for the problems where DP requires an exponential number of states, the corresponding LP formulation consists of an exponential number of constraints. This difficulty necessitates research on new techniques to reduce the state space of DP by eliminating the states

and decisions that will not lead to the optimal policy.

As each problem requires a specific DP formulation and a program to be solved, LP provides an advantage of easily writing and solving tractable DP models using commercial software. Furthermore LP enables us to use sensitivity analysis for dynamic programs. LP sensitivity analysis and its relation to the states and decisions of the dynamic program could be further investigated. Another direction for research is utilization of LP formulation of DP in order to obtain stronger IP formulations in discrete optimization. This article is closely related to the following articles in the encyclopaedia are **Approximate Dynamic Programming I: Modeling; Approximate Dynamic Programming—II: Algorithms; Computation and Dynamic Programming and Dynamic Programming, Control, and Computation**.

DYNAMIC PROGRAMMING IN CONTINUOUS-TIME

Dynamic programming in the application areas of operations research often arise from optimal objectives such as to minimize costs, maximize profits, or maximize the utility of wealth and its consumption. These problems are invariably formulated in an uncertain environment since deterministic problems rarely occur without some sort of random perturbation. Hence, the optimization will necessarily be over an expected or mean value, else an optimum will not be well-posed. Assuming that the perturbing noise is Markovian, then Bellman's [1] principle of optimality fits both stochastic and deterministic environments, with just some extra analysis in the stochastic case. As a result of taking expectation before optimization, the equation of dynamic programming is a deterministic partial integro-differential equation (PIDE). See Hanson [2,3] or Kushner and Dupuis [4] for more details.

Assuming that the objective is a minimal expected cost problem and that the minimum is unique, then the minimum cost [3], starting at any time t in the horizon $[t_0, t_f]$, is

$$v^*(\mathbf{x}, t) \equiv \min_{\mathbf{U}(t, t_f)} \left[\mathbb{E}_{(W, P)(t, t_f)} \right]$$

$$\times \left[V[\mathbf{X}, \mathbf{U}, t_f](\mathbf{x}, t) \middle| \mathbf{X}(t) = \mathbf{x}, \right. \\ \left. \mathbf{U}(t) = \mathbf{u} \right],$$

$$V[\mathbf{X}, \mathbf{U}, t_f](\mathbf{x}_0, t) = \int_t^{t_f} C(\mathbf{X}(s), \mathbf{U}(s), s) ds \\ + Z(\mathbf{X}(t_f), t_f), \quad (1)$$

where the value of the total cost on $(t, t_f]$ is based on cumulative running cost $C(\mathbf{x}, \mathbf{u}, t)$ and final cost $Z(\mathbf{x}, t_f)$ functions. The $\mathbf{X}(t)$ is the state n_x -vector process on state domain $\mathcal{D}_x$, $\mathbf{U}(t)$ is the control n_u -vector process or optimizing variable on control domain $\mathcal{D}_u$. The set $\{\mathbf{W}(t), \mathbf{P}(t)\}$ comprise fundamental Markov diffusion and jump processes. The diffusion component characterizes the central continuous part and the jump part characterizes the large random, instantaneous, discontinuous rare events, since the diffusion part is insufficient for modeling catastrophic risk events. Obviously, the final optimal value is given by $v^*(\mathbf{x}, t_f) = Z(\mathbf{x}, t_f)$, for any $\mathbf{x} \in \mathcal{D}_x$ from setting $t = t_f$ in Equation (1).

The stochastic dynamic constraint is the jump-diffusion stochastic differential equation (SDE),

$$d\mathbf{X}(t) = \mathbf{f}(\mathbf{X}(t), \mathbf{U}(t), t) dt \\ + g(\mathbf{X}(t), \mathbf{U}(t), t) d\mathbf{W}(t) + d\mathbf{J}(t), \\ \mathbf{J}(t) = \int_0^t \int_{\mathcal{D}_q} h(\mathbf{X}(t), \mathbf{U}(t), t, \mathbf{q}) \mathcal{P}(d\mathbf{t}, d\mathbf{q}), \\ \mathbf{P}(t) = \int_0^t \int_{\mathcal{D}_q} \mathcal{P}(d\mathbf{t}, d\mathbf{q}), \quad (2)$$

when $t_0 \leq t \leq t_f$ subject to a given initial state $\mathbf{X}(t_0) = \mathbf{x}_0$, $d\mathbf{W}(t)$ is the n_w -dimensional differential diffusion or Wiener process, $\mathcal{P}(d\mathbf{t}, d\mathbf{q})$ is the compound n_p -dimensional Poisson random measure that introduces the Poisson random jump times for the time infinitesimal measure $d\mathbf{t} = (t, t + dt]$ and underlying

n_p -dimensional random jump amplitude variables in $d\mathbf{q} = (\mathbf{q}, \mathbf{q} + d\mathbf{q})$ when there is a jump. The diffusion process is normally distributed with zero infinitesimal mean $E[d\mathbf{W}(t)] = \mathbf{0}$, but correlation between components is allowed, $\text{Cov}[d\mathbf{W}(t), d\mathbf{W}^\top(t)] = [\rho_{ij}(t)]_{n_w \times n_w} dt$, such that $\rho_{i,i}(t) = 1$. The usual Poisson process is denoted by $\mathbf{P}(t)$, such that it is Poisson distributed with vector jump intensity $\lambda(t)$, infinitesimal moments $E[d\mathbf{P}(t)] = \lambda(t)dt = [\lambda_i(t)]_{n_p \times 1} dt$, $\text{Cov}[d\mathbf{P}(t), d\mathbf{P}^\top(t)] = [\lambda_i(t)\delta_{ij}]_{n_p \times n_p} dt$ and $E[\mathcal{P}_j(d\mathbf{t}, d\mathbf{q})] = \lambda_j(t)dt\phi_{Q_j}(q_j)dq_j$, assuming no correlations between Poisson component processes, since simultaneous jumps are unlikely. The underlying jump amplitude random variables Q_j are IID for each component $j = 1:n_p$ with density $\phi_{Q_j}(q_j)$. Similarly, there are no correlations between Poisson and Wiener processes. The Poisson jumps are by definition instantaneous, so at the instant of a jump, there is zero time for continuous change and hence the discontinuous changes are being calculated independent of continuous changes. At the k th jump of j th Poisson component $P_j(t)$ at random time $T_{j,k}$ with random mark $Q_{j,k}$, $\mathbf{X}(t)$ jumps by the amplitude

$$\begin{aligned} \mathbf{X}(T_{j,k}) - \mathbf{X}(T_{j,k}^-) &= \hat{\mathbf{h}}_j(\mathbf{X}(T_{j,k}^-), \mathbf{U}(T_{j,k}^-), T_{j,k}^-, q_{j,k}) \\ &\equiv \left[h_{ij}(\mathbf{X}(T_{j,k}^-), \mathbf{U}(T_{j,k}^-), \right. \\ &\quad \left. T_{j,k}^-, q_{j,k}) \right]_{n_x \times 1}, \end{aligned}$$

where the function $h(\mathbf{x}, \mathbf{U}, t, \mathbf{q})$ is the $n_x \times n_p$ jump amplitude coefficient array. Like for diffusions, the jump-diffusion approximation consistency conditions require that the increment version of $d\mathbf{X}(t)$ in Equation (2) have conditional infinitesimal mean and variance that are $E[\Delta\mathbf{X}(t)|\mathbf{X}(t)] = O(\Delta t)$ and $\text{Var}[\Delta\mathbf{X}(t)|\mathbf{X}(t)] = O(\Delta t)$. The drift or mean appreciation coefficient function is $\mathbf{f}(\mathbf{x}, \mathbf{U}, t)$ and the diffusion coefficient function is $\mathbf{g}(\mathbf{x}, \mathbf{U}, t)$, both, along with $h(\mathbf{x}, \mathbf{U}, t, \mathbf{q})$, are assumed to be bounded for computational feasibility and commensurate in multiplication with respect to the other variables. Stronger existence results are available assuming Lipschitz continuity, but some important models such as for stochastic volatility are non-Lipschitzian. For pure

deterministic problem, set $g \equiv 0$ and $h \equiv 0$, while for diffusion only noise set $h \equiv 0$.

Assuming that minimization and expectation operators are decomposable into factors, then Bellman's principle of optimality [3] is

$$\begin{aligned} v^*(\mathbf{x}, t) &= \min_{\mathbf{U}(t, t+\delta t)} \left[\begin{aligned} &E_{(\mathbf{W}, \mathbf{P})(t, t+\delta t)} \\ &\times \left[\int_t^{t+\delta t} C(\mathbf{X}(s), \mathbf{U}(s), s) ds \right. \\ &\left. + v^*(\mathbf{X}(t+\delta t), t+\delta t) \mid \mathbf{X}(t) = \mathbf{x}, \right. \\ &\quad \left. \mathbf{U}(t) = \mathbf{u} \right] \end{aligned} \right], \end{aligned} \quad (3)$$

given some small time step δt , leads in the limit to the Hamilton–Jacobi–Bellman (HJB) equation of stochastic dynamic programming (SDP), keeping only δt -terms,

$$\begin{aligned} 0 &= v_t^*(\mathbf{x}, t) + \min_{\mathbf{u}} [\mathcal{H}(\mathbf{x}, \mathbf{u}, t)] \\ &\equiv v_t^*(\mathbf{x}, t) + \mathcal{H}^*(\mathbf{x}, t), \end{aligned} \quad (4)$$

where the *Hamiltonian* functional is given by

$$\begin{aligned} \mathcal{H}(\mathbf{x}, \mathbf{u}, t) &\equiv C(\mathbf{x}, \mathbf{u}, t) + \nabla_{\mathbf{x}}^\top [v^*](\mathbf{x}, t) \cdot \mathbf{f}(\mathbf{x}, \mathbf{u}, t) \\ &\quad + \frac{1}{2} \text{Tr} [(gRg^\top)(\mathbf{x}, \mathbf{u}, t), \\ &\quad \nabla_{\mathbf{x}} [\nabla_{\mathbf{x}}^\top [v^*]](\mathbf{x}, t)] \\ &\quad + \sum_{j=1}^{n_p} \lambda_j(t) \int_{\mathcal{D}_q} [v^*(\mathbf{x} + \hat{\mathbf{h}}_j \\ &\quad \times (\mathbf{x}, \mathbf{u}, t, q_j), t) - v^*(\mathbf{x}, t)] \\ &\quad \times \phi_{Q_j}(q_j) dq_j, \\ R = R(t) &\equiv [\delta_{ij} + \rho_{ij}(t)(1 - \delta_{ij})]_{n_w \times n_w}, \\ \text{Tr}[A, B] &\equiv \sum_{i=1}^n \sum_{j=1}^n A_{ij} B_{ij}. \end{aligned} \quad (5)$$

Along with appropriate boundary conditions, the function completes the formal specification of the boundary-final value problem, the final value condition, and the placement of the time derivative implying that the dynamic programming problem is backward in time. Thus, the HJB equation (4) is, in general, a functional PIDE, so possesses

properties beyond the usual partial differential equations (PDEs) in that there is global dependence due to the integral properties whereas the partial derivatives impart only local dependence. In addition, the minimization can introduce nonlinear behavior, as in the case of the often assumed quadratic control costs. These and other properties lead to many computational problems beyond the usual linear PDE.

For specification of the minimization of the Hamiltonian in Equation (5), unique minimum and continuous control derivatives are up to second-order such that the Hessian is positive-definite; that is, $\nabla_u[\nabla_u^\top[\mathcal{H}]](\mathbf{x}, \mathbf{u}, t) > 0$ are assumed. The critical condition $\nabla_u[\mathcal{H}](\mathbf{x}, \mathbf{u}, t) = \mathbf{0}$ yields the unconstrained minimal or regular control $\mathbf{u}^{(\text{reg})}(\mathbf{x}, t) = \text{argmin}_{\mathbf{u}}[\mathcal{H}(\mathbf{x}, \mathbf{u}, t)]$, the primary in purely mathematical problems, but a preliminary to the constrained optimal control in applications. Real problems have constraints, so assuming hypercube constraints for simplicity, that the constrained optimal control $\mathbf{u}^*(\mathbf{x}, t)$ satisfies the constraints $U_i^{(\min)} \leq u_i^*(\mathbf{x}, t) \leq U_i^{(\max)}$ for $i = 1:n_u$ components. Thus,

$$\mathbf{u}^*(\mathbf{x}, t) = \left[\min \left[\max \left[u_i^{(\text{reg})}(\mathbf{x}, t), U_i^{(\min)} \right], U_i^{(\max)} \right] \right]_{n_u \times 1}. \quad (6)$$

COMPUTATIONAL REDUCING CANONICAL FORMS

There are some simplifications that can be used to make the computation of the optimal control simpler. An example is to use a linear drift dynamics and quadratic control cost model; that is, a linear quadratic (LQ) model in control only [3], so that

$$\begin{aligned} \mathbf{f}(\mathbf{x}, \mathbf{u}, t) &= \mathbf{f}_0(\mathbf{x}, t) + \mathbf{f}_1(\mathbf{x}, t)\mathbf{u}, \\ g(\mathbf{x}, \mathbf{u}, t) &= g_0(\mathbf{x}, t), h(\mathbf{x}, \mathbf{u}, t, q) = h_0(\mathbf{x}, t, q), \\ C(\mathbf{x}, \mathbf{u}, t) &= c_0(\mathbf{x}, t) + c_1(\mathbf{x}, t)\mathbf{u} + \mathbf{u}^\top c_2(\mathbf{x}, t)\mathbf{u}, \\ \mathcal{H}(\mathbf{x}, \mathbf{u}, t) &= \mathcal{H}_0(\mathbf{x}, t) + \mathcal{H}_1(\mathbf{x}, t)\mathbf{u} \\ &\quad + \frac{1}{2}\mathbf{u}^\top \mathcal{H}_2(\mathbf{x}, t)\mathbf{u}, \end{aligned} \quad (7)$$

where all functions are assumed to be specified and that c_2 is positive definite. Since c_2 and $\mathcal{H}_2$ appear only in quadratic forms, they might as well be symmetric, then the regular optimal control is explicit,

$$\begin{aligned} \mathbf{u}^{(\text{reg})}(\mathbf{x}, t) &= -c_2^{-1}(\mathbf{x}, t)(c_1^\top(\mathbf{x}, t) \\ &\quad + f_1^\top(\mathbf{x}, t)\nabla_x[v^*](\mathbf{x}, t)), \end{aligned} \quad (8)$$

and the optimal control $\mathbf{u}^*(\mathbf{x}, t)$ is still given by the formula in Equation (6).

In the classical LQ case, that is LQ in both control and state spaces, both the Hamiltonian and the optimal value v^* are quadratics, $\mathcal{H}$ in both control and state, while v^* can be shown to be a quadratic in state alone, so that the solution for v^* involves solving ODE final value problems only for coefficient functions of time t (see Refs 3 and 5 for the well-known details).

FINITE DIFFERENCE PDE COMPUTATIONAL METHODS

Finite differences have the advantage of straightforward application, but with a significant difficulty in convergence if the ratio of the time to space meshes is not sufficiently small. The first step is the discretization, where the time $t \in [t_0, t_f]$ is partitioned into N_t discrete backward time nodes and assuming for simplicity that the spatial variable is one-dimensional ($n_x = 1$) for $x \in [x_0, x_f]$,

$$\begin{aligned} T_k &= t_f - (k - 1) \cdot \Delta T \quad \text{for } k = 1:N_t, \\ &\quad \text{with } \Delta T \equiv (t_f - t_0)/(N_t - 1), \\ X_j &= x_0 + (j - 1) \cdot \Delta x \quad \text{for } j = 1:N_x, \\ &\quad \text{with } \Delta X \equiv (x_f - x_0)/(N_x - 1). \end{aligned}$$

Next central finite differences (CFD) are used for second-order accuracy for spatial derivatives included in the Crank–Nicolson implicit (CNI) method along with half-steps in time to obtain a simple second-order accurate form for the time derivative,

$$\begin{aligned}
v^*(X_j, T_k) &\rightarrow V_{j,k}, \\
v_i^*(X_j, T_{k+0.5}) &\rightarrow (V_{j,k+1} - V_{j,k})/(-\Delta T), \\
v_x^*(X_j, T_k) &\rightarrow \Delta DV_{j,k} = 0.5(V_{j+1,k} - V_{j-1,k})/\Delta x, \\
v_{xx}^*(X_j, T_k) &\rightarrow DDV_{j,k} = (V_{j+1,k} - 2V_{j,k} + V_{j-1,k})/(\Delta x)^2, \\
u^{(\text{reg})}(X_j, T_k) &\rightarrow UR_{j,k} = -(C_{1,j,k} + F_{1,j,k} \Delta DV_{j,k})/C_{2,j,k}, \\
u^*(X_j, T_k) &\rightarrow US_{j,k} = u_0(UR_{j,k}) = \min[\max[UMIN, UR_{j,k}], UMAX], \\
v^*(X_j + h_0(X_j, T_k, q), T_k) &\rightarrow VH_{j,k}(q) \& \Lambda_k = \lambda(T_k), \\
F_{i,j,k} = f_i(X_j, T_k) &\& C_{i,j,k} = c_i(X_j, T_k) \& G_{0,j,k} = g_0(X_j, T_k), \\
F_{j,k} = f(X_j, US_{j,k}, T_k) &\& C_{j,k} = c(X_j, US_{j,k}, T_k), \\
UMIN = U^{(\min)} &\& UMAX = U^{(\max)},
\end{aligned} \tag{9}$$

where the LQ assumption has been used for explicitness in the optimal control or otherwise different procedures will be needed [3]. The integral part for the jump amplitude distribution is probably not familiar and requires at least linear interpolation between a postjump position and nearest nodes, so

$$\begin{aligned}
IVH_{j,k} &\equiv \int_{\mathcal{D}_q} VH_{j,k}(q) \phi_Q(q) dq \\
&\simeq \sum_{i=1}^{N_q} w_i \cdot ((1 - \theta_i) V_{j+\ell_i,k} + \theta_i V_{j+\ell_i+1,k}),
\end{aligned} \tag{10}$$

where the $\{j + \ell_i, j + \ell_i + 1\}$ are the nearest-neighbor x -nodes corresponding to the postjump position $X_j + h_0(X_j, T_k, q_i)$ for $i = 1:N_q$ mark nodes, the θ_i are the corresponding linear interpolation weights and the w_i are the numerical integration weights assigned to the mark nodes q_i with respect to the density $\phi_Q(q)$. See Ref. 3 for additional information, procedures, and examples.

The basic CNI step approximates the midpoint in backward time by the average preserving second-order accuracy,

$$\begin{aligned}
V_{j,k+1} &\simeq V_{j,k} + \Delta T \cdot \mathcal{H}_{j,k+0.5} \simeq V_{j,k} \\
&\quad + 0.5 \Delta T \cdot (\mathcal{H}_{j,k} + \mathcal{H}_{j,k+1}), \\
\mathcal{H}_{j,k} &= C_{j,k} + F_{j,k} DV_{j,k} \\
&\quad + 0.5 G_{0,j,k}^2 DDV_{j,k} + \Lambda_k (IVH_{j,k} - V_{j,k}).
\end{aligned} \tag{11}$$

Although Crank–Nicolson is unconditionally stable and has significant algebraic simplifications for linear diffusions problems, the general complexity of the jump-diffusion

problem with quadratic costs here requires iterations to handle the nonlinearities and jump integrals in the optimal value function. An extrapolated predictor–corrector method has been found to be robust for a variety of applications [3]. An abbreviated pseudoalgorithm for the method is as follows:

1. Given constants: $\{N_t, N_x, N_q, N_\gamma, \text{tol}_v, t_f, \text{UMIN}, \text{UMAX}, x_0, x_f\}$;
2. Get $T_k \forall k$; Get $X_j, \forall j$;
3. Given functions: $\{c_0, c_1, c_2, f_0, f_1, g_0, h_0, \lambda_0, u_0, Z\}$;
4. Get $V_{j,1} = Z(X_j, t_f) \forall j$; Get $\Lambda_k = \lambda_0(T_k), \forall k$;
5. For $k = 1:N_t - 1$ do;
6. Extrapolation step: $V_{j,k+0.5}^{(1)} = V_{j,1}$; If $k > 1$, then $V_{j,k+0.5}^{(1)} = 0.5(3V_{j,k} - V_{j,k-1})$, endif; plus $\mathcal{H}_{j,k+0.5}^{(1)} \forall j$, using Equation (11);
7. Prediction step: $V_{j,k+1}^{(2)} = V_{j,k} + \Delta T \cdot \mathcal{H}_{j,k+0.5}^{(1)} \forall j$;
8. Predictor evaluation step: $V_{j,k+0.5}^{(2)} = 0.5(V_{j,k+1}^{(2)} + V_{j,k})$, plus $\mathcal{H}_{j,k+0.5}^{(2)} \forall j$, using Equation (11);
9. For $\gamma = 2:N_\gamma$ do;
10. Correction steps: $V_{j,k+1}^{(\gamma+1)} = V_{j,k} + \Delta T \cdot \mathcal{H}_{j,k+0.5}^{(\gamma)} \forall j$;
11. Corrector convergence check step given sufficient relative tolerance tol_v :

$$\text{If } \max_j [V_{j,k+1}^{(\gamma+1)} - V_{j,k+1}^{(\gamma)}] < \text{tol}_v$$

$$\cdot \max_j [V_{j,k+1}^{(\gamma)}]$$

then $k = k + 1, V_{j,k+1} = V_{j,k+1}^{(\gamma+1)}, \forall j$,
break from loop γ to return to step 6;
endif;

12. Corrector evaluation step: $V_{j,k+0.5}^{(\gamma+1)} = 0.5(V_{j,k+1}^{(\gamma+1)} + V_{j,k})$, plus $\mathcal{H}_{j,k+0.5}^{(\gamma+1)}$, $\forall j$, using Equation (11);
13. end loop γ ;
14. end loop k .

However, more discussion of stability and its effect on convergence is needed. Using the CFD for the first-order derivative in Equation (9) means that diffusion dominance has been tacitly assumed and the time step is selected by a mesh ratio condition, that is,

$$\min_{j,k} [G_{0,j,k}^2 - |F_{j,k}| \Delta x] \geq 0, \quad (12)$$

$$\Delta T < (\Delta x)^2 / \max_{j,k} [G_{0,j,k+0.5}^2].$$

If the jump-diffusion is not diffusion dominated, then it is advisable to use an unwinding finite difference for the first-order difference to correspond to the direction of the drift,

$$DV_{j,k} = (V_{j+s,k} - V_{j,k}) / (s\Delta x),$$

$$s = \text{sgn}(F_{j,k}), \quad \text{sgn}(0) \equiv 1, \quad (13)$$

even though this approximation is only first order in Δx . Second-order forward and backward finite differences of second-order in Δx can be used as they would be used for derivative boundary conditions [3] to preserve second-order accuracy.

SDP can become computationally demanding as the state dimension n_x and the common number of nodes per dimension N_x grow, as it does with PDEs, because the demand per time step grows exponentially with exponent $n_x \ln(N_x)$ and this growth is called *Bellman's Curse of Dimensionality* [3]. Advanced computing techniques like massively parallel and vector processor are needed to treat large dimensions [2].

PROBABILISTIC MARKOV CHAIN APPROXIMATION

The Markov chain approximation (MCA) [4,6] uses the discrete Markov chain process transition probabilities implied by finite differences to generate proper computational time

steps and weak convergence properties, developed by Kushner in the 1970s. This method, as in the previous section, is applicable to deterministic as well as stochastic processes of the Markov type.

Assuming the same optimization model 1 and stochastic dynamics (Eq. 2), but $n_x = 1$ and $n_u = 1$, the Bellman SDP equation (4) with Equation (5) and forward discrete-time value function $V_k(x) \simeq v^*(x, t_k)$ becomes

$$V_{k-1}(x) = V_k(x) + \Delta t_{k-1} \min_u [C_k(x, u) + F_k(x, u)V'_k(x) + \frac{1}{2}G_k^2(x)V''_k(x) + \Lambda_k(\text{IVH}_k(x) - V_k(x))], \quad (14)$$

for $k = 1:N_t - 1$, $\Delta t_{k-1} = t_k - t_{k-1}$, $t_1 = t_0$, $t_{N_t} = t_f$, and $V_1(x) = Z(x, t_f)$, using similar notation of the previous sections. Let ξ_k denote the k th stage of the Markov chain for $k = 1:N_1$ such that $\Delta \xi = \xi_{k+1} - \xi_k = O(\Delta x)$. The Markov chain transition probabilities must satisfy the proper conditions of non-negativity and conservation of probability, as well the jump-diffusion approximation $O(\Delta t_k)$ consistency conditions mentioned in the section titled "Dynamic Programming in Continuous-Time."

For the self or nearest-neighbor transition probabilities associated with the diffusion component processes and the finite difference grid with step ΔX using the central form for $v''_k(x)$ as in Equation (9) and the stabilizing upwinded form for $v'_k(x)$ as in Equation (13) with $s = \text{sgn}(f_k(x, u))$,

$$p_k^{(D)}(X, X|X = x, u_{k-1})$$

$$= 1 - \Delta t_{k-1} \left(g_k^2(x) + \Delta x |f_k(x, u_{k-1})| \right) / (\Delta x)^2,$$

$$p_k^{(D)}(X, X \pm \Delta x |X = x, u_{k-1})$$

$$= \Delta t_{k-1} \left(0.5g_k^2(x) + \Delta X \max[\pm f_k(x, u_{k-1})] \right) / (\Delta x)^2. \quad (15)$$

The global time interpolation mesh condition for diffusive convergence is

$$\Delta t_{k-1} \leq (\Delta x)^2 / \min_{x,u} \left[g_k^2(x) + \Delta x |f_k(x, u_{k-1})| \right]. \quad (16)$$

Provided that this time step is sufficiently small, then the well-known infinitesimal

Poisson transition probabilities, for $j = 0, 1, 2$ or more jumps, are given by

$$p_{j,k}^{(j)} = \begin{cases} 1 - \lambda_k \Delta t_{k-1} + o(\lambda_k \Delta t_{k-1}), & j = 0 \text{ jumps} \\ \lambda_k \Delta t_{k-1} + o(\lambda_k \Delta t_{k-1}), & j = 1 \text{ jump} \\ o(\lambda_k \Delta t_{k-1}), & j \geq 2 \text{ jumps,} \end{cases} = p_{0,k}^{(j)} \delta_{j,0} + p_{1,k}^{(j)} \delta_{j,1} + o(\lambda_k \Delta t_{k-1}), \quad (17)$$

more specifically for the mean jump count $\lambda_k \Delta t_{k-1} \ll 1$ and ignoring the $o(\lambda_k \Delta t_{k-1})$ yields the 0–1 Bernoulli process transition probability terms, $\{p_{0,k}^{(j)} = 1 - p_{1,k}^{(j)}, p_{1,k}^{(j)} = \lambda_k \Delta t_{k-1}\}$, that are consistent with the jump-diffusion approximation. Finally, adding the transition probability for the node-interpolated jump amplitude when there is a jump leading to this MCA dynamic programming computation formulation.

$$V_{k-1}^{(JD)}(x) \simeq \min_u \left[C_k(x, u) \Delta t_{k-1} + p_{0,k}^{(j)} \sum_{\ell=1}^3 p_k^{(D)} \right. \\ \times (x, x + (\ell - 2) \Delta x | x, u) V_k^{(JD)} \\ \left. \times (x + (\ell - 2) \Delta X) + p_{1,k}^{(j)} \widetilde{IVH}_k^{(JD)}(x, u) \right], \quad (18)$$

where $\widetilde{IVH}_k^{(JD)}$ is the node-interpolated version of the integral interpolation in Equation (10). For more details, see Kushner and Dupuis [4].

SUMMARY AND SOME OTHER APPROACHES

This article covers the fairly general computational SDP for Markov stochastic processes, that includes deterministic, diffusion, and jump-diffusion models as subsets. Due to space limitations, it has not been possible to cover some related topics. There have been recent results for convergence rates of computational dynamic programming in diffusion problems, most recently by Song and Yin [7], who also refer to prior convergence

rate work of others. Genuine stochastic difference equation models have not been covered, but Sennott [8] supplies a wealth of discrete applications and other kinds of objective functions. See also the section in Ref. 2 reviewing the discrete version of differential dynamic programming with alternative backward and forward successive approximations.

DYNAMIC VEHICLE ROUTING

BARRETT W. THOMAS

Department of Management Sciences,
Tippie College of Business,
University of Iowa, Iowa City, Iowa

This article addresses vehicle routing problems in which some problem information is dynamic. Dynamic information is information that becomes known over the problem horizon, where the problem horizon is the period of time during which customer visits can actually take place. For example, the volume of a customer's demand may be unknown until a vehicle visits the customer, or in some cases, who all of the customers are may be unknown until the vehicle is actually on the road. In many problem variants, there may be some knowledge of the dynamic information in advance, usually in the form of a probability distribution. For instance, while the volume of a customer's demand may be unknown until the customer is visited, its demand can be described with a particular probability distribution whose parameters can be estimated through historical data. Because the scope of routing problems is wide, this discussion is limited to problems in which a set of customers is served by a fleet of vehicles, potentially a fleet of a single vehicle, that may or may not be capacity constrained.

Recent years have seen numerous innovations in dynamic vehicle routing methodologies and applications. In part, this innovation has been driven by the fact that computing power and mobile communication technology have made real-world implementations a reality. Only 15 years ago, for example, it was common for drivers of local pickup and delivery routes to need to seek out pay phones in order to receive information about new requests for service. The result was that dispatchers were limited in the routing changes that could be made as new information became known. Now, with mobile phones ubiquitous, new information and routing changes can be communicated

instantaneously. Further, computing power has reached the point in both speed and availability that even small companies have the ability to employ decision-support technology. Finally, companies can combine the computing power with inexpensive data storage to capture and to exploit historical information in planning for the future.

Examples of the growing use of dynamic vehicle routing can be found in multiple industries and throughout the world. For example, Bieding *et al.* [1] describe a dynamic routing problem that emerges for a German newspaper publisher who needs to supply newspapers to subscribers who, for whatever reason, did not receive a paper via the regular morning delivery. du Plessis [2] uses dynamic routing to improve operations for a South Africa-based autocarrier. Erera *et al.* [3] developed a dynamic routing scheme for an Atlanta-based beverage distributor. Attanasio *et al.* [4] demonstrate how the combination of real-time information, handheld computers, and decision support improve the operations of a London-based courier service. Flatberg *et al.* [5] discuss the case of the local freight pickup and delivery operations of a Norwegian distribution company. Applications of dynamic vehicle routing are not confined to commercial deliveries. An excellent example is the routing of unmanned aerial vehicles in sensor network monitoring [6]. Outside of routing, readers may be interested in examples of dynamic problems in fleet management [7,8], multiperiod routing [9,10], ambulance deployment [11], inventory routing and dispatching [12–14], energy dispatching [15], scheduling [16,17], and military operations [18].

This article is organized around the solution methodologies for dynamic routing problems. Readers interested in an in-depth classification of dynamic vehicle routing problem variants are referred to Ref. 19 with a comprehensive taxonomy of vehicle routing problems found in Ref. 20. Larsen *et al.* [21] provide a review of the recent dynamic vehicle routing literature, particularly focused

on problem variants. The solution methodologies for dynamic vehicle routing problems can be characterized by two properties. First, we characterize the solution methodologies by the restrictions that they place on the structure of the solutions to their respective dynamic routing problems. Second, we can characterize the solutions by the extent to which they use known information.

Because of the complex nature of most dynamic routing problems, even modern computing is limited to only the smallest problems in its ability to find exact solutions. In particular, most exact solutions require identifying what action should be taken for any possible situation that might arise over the problem horizon. This set of actions is known as a *policy*. The number of situations may number in the billions, and for complex problems, the number of possible actions for a given situation could number in the millions. Often, the resulting optimal policy cannot even be stored in memory. Hence, most dynamic routing problems are solved via heuristic solution methods. A common distinction among these heuristics is what restrictions they place on the structure of the solutions. In essence, the computational challenge of computing an optimal policy is diminished by restricting the number of situations and actions that need to be considered. There are three general categories of restrictions: a priori, insertion, and unrestricted.

A *a priori* or fixed route policies rely on the use of a route or routes constructed in advance, before any dynamic information is revealed. Essentially, a priori restrictions simplify the solution of the dynamic problem by transforming it into a static one. To account for the realization of random events, a priori methods rely on recourse rules. For example, customers who do not require service during the problem horizon are skipped when reached on the a priori tour. A priori restrictions require that all possible customers are known in advance. *Insertion* restrictions develop a routing policy by inserting newly arriving service requests into an existing tour. In the case in which some subset of service requests is known in advance of the problem horizon, an initial tour is constructed, into which requests will

be inserted when the vehicle or vehicles is en route. Insertion-restricted methodologies can be described as real time. That is, they are designed to make decisions as the vehicle is en route and to make decisions for only those situations that are actually encountered. As the name implies, *unrestricted* routing policies do not impose, in advance, a particular structure on the final solution. Notably, no customer order is fixed at any point in the problem horizon.

While both the a priori and the insertion restrictions have some limitations in the problem variants to which they can be applied, neither is limited by a problem's objective function. In dynamic vehicle routing, the most common objective functions are either the minimization of some measure of routing cost or the maximization of customer service. The former is a natural extension of the travel cost—minimization objective common in deterministic routing problems. However, the service-maximization objective has become increasingly common. There are multiple reasons for the shifting objective functions. One reason is that the cost structure in dynamic vehicle routing, because it is often a local operation, is likely to have much higher costs associated with labor than with travel [22,23]. Further, these labor costs are essentially fixed. Hence, it is advantageous to spread the labor costs over as many customers as possible. Second, in dynamic environments, minimizing travel costs can lead to suboptimal performance in increasingly important service metrics [24]. This issue is particularly relevant in service businesses subject to long-term customer relationships. The ability to renew the relationships is often directly tied to the ability to meet customer expectations [25]. Failure to meet the expectations can result in the loss of business to competitors.

In this article, we consider two ways in which solution methods can account for problem information. For one, solutions can be constructed without regard to future information. We call such solution methodologies *myopic*. Contrarily, solutions can be constructed so as to account for the fact that the problem information is revealed over

time. We call such solution methodologies *anticipatory*.

The two-dimensional characterization of dynamic routing solution structures results in six categories. The remainder of this article will be devoted to discussing these in more detail. Each section covers one of the three solution structures with subsections for the information use. We discuss, in more detail, a priori strategies in the first section, and insertion-restricted solutions in the second section. The third section discusses unrestricted solution methods. This article concludes with a discussion of emerging challenges in the real-world implementation of dynamic routing solutions.

A PRIORI

An a priori route is one in which all customers are sequenced in advance of the active time horizon. Thus, a priori-restricted solutions are limited to problems in which all potential customers are known in advance. To compensate for realizations of the random events, prespecified recourse rules are used. Recourse rules are rules that specify what is to happen when a problem constraint is violated during the course of the problem horizon. An example is that a vehicle is required to return to the depot to unload if it reaches capacity before the end of the a priori route that it is following.

It is important to note that, while they are used as solutions to dynamic problems, a priori solutions are themselves static. That is, the sequence of customers visits remains the same regardless of what new information is learned over the problem horizon. This feature of the solution structure is what simplifies the solution process. In particular, the solution can be stored as a vector or matrix that is easily manipulated in a local-search procedure.

The quintessential example of an a priori routing problem is the a priori solution to the probabilistic traveling salesman problem (PTSP), first introduced in Ref. 26. In the PTSP, a set of customers must be sequenced keeping in mind that not every customer will need to be visited every day. The problem differs from the deterministic traveling

salesman problem in that there is a known probability for whether or not a customer will require service on a given day. In the case that a customer does not need to be serviced on a particular day, the recourse is to skip the customer when the tour is implemented.

As an example of the PTSP, consider a set of customers $\{1, 2, 3, 4, 5, 6, 7, 8\}$. An a priori solution orders the customers in advance, say $3 \rightarrow 8 \rightarrow 5 \rightarrow 7 \rightarrow 2 \rightarrow 6 \rightarrow 4 \rightarrow 1$. Suppose that on a given day, only customers 2, 4, 6, and 7 need service. In that case, the vehicle would serve the customers in the order $7 \rightarrow 2 \rightarrow 6 \rightarrow 4$, the order prescribed by the a priori solution but with customers 1, 3, 5, and 8 skipped.

In the case of both the literature on myopic and anticipatory a priori restrictions, rarely do authors present the problem as a dynamic problem. Rather, the problem description assumes the a priori solution structure. In some cases, perhaps because of managerial implications or technological limitations at the time of writing, such a restriction may truly describe the available solution set. As noted previously, however, information technology and computing power now allow for the possibility of less restricted solutions. Yet, regardless of whether or not the method was originally developed for a dynamic problem or not, existing a priori solution methods can still play a role in the solution of dynamic problems.

Myopic

A myopic a priori routing solution is one that assumes that all problem information is deterministic. For instance, consider our previous example of the PTSP. A myopic solution to the problem would assume, in determining the a priori tour, that all customers are going to be visited everyday. The problem then becomes the traveling salesman problem, although in implementation a recourse is still required. Jaillet [26] provides an example demonstrating the poor quality that can result from myopic solution to the PTSP. Campbell and Thomas [27] and Chen *et al.* [28] empirically demonstrate the outcome for variants of the PTSP.

The volume of deterministic routing literature is vast. For an introduction, the reader is referred to Refs 29, 30.

Anticipatory

The anticipatory a priori routing literature is voluminous. In addition to Ref. 26, foundational work in a priori routing can be found in Refs 31, 34. A review of the a priori routing literature can be found in Ref. 35. An important feature of the recent literature is that, even with modern computing power and an a priori restriction on solution structure, exact solutions are limited to small problems [36]. Recent work in a priori routing has explored the improvement of solution quality while still maintaining the basic structure of an a priori routing solution. For example, Ak and Erera [37] introduce a new recourse scheme for the stochastic vehicle routing problem that allows for two vehicles to share the work of each other's routes, thus taking advantage of variance pooling. Other recent work considers robust optimization (minimizing worst-case outcomes) in the context of a priori routing [38,39]. This work differs from much of the rest of the literature in which the focus is on minimizing expected costs.

INSERTION

Solution methodologies framed around insertion restrictions have a rich history in the routing literature. Insertion-restricted solutions maintain a route or routes throughout the problem horizon. As new service requests become known, the requests are inserted into one of the existing routes. The nature of the solution structure requires that insertion-restricted solutions be limited to problems in which customer service needs become known during the problem horizon.

As a concrete example, consider a single vehicle that must serve a set of customers $\{1, 2, 3, 4, 5, 6, 7, 8\}$. At some point in the problem horizon, some set of customers, say $\{2, 3, 5, 6, 7\}$, will have requested service. With an insertion-restricted solution, an order of the customers say $3 \rightarrow 5 \rightarrow 7 \rightarrow 2 \rightarrow 6$ would exist. Suppose that the next customer who requests

service is customer 8. In the case of an insertion-restricted solution, the relative order already existing for the customers ($3 \rightarrow 5 \rightarrow 7 \rightarrow 2 \rightarrow 6$) would be maintained, and customer 8 is routed according to some rule that inserts it into the existing order. The result is the tour $3 \rightarrow 8 \rightarrow 5 \rightarrow 7 \rightarrow 2 \rightarrow 6$.

In practice, the advantage of insertion-restricted solution approaches arises from the ability to quickly make decisions in real time. For example, consider minimum cost insertion (identifying the two customers in the tour between whom adding the new request will add the least additional travel distance). Computing the point of insertion can be done quickly and with minimal computation. Another advantage of the insertion technique is that it keeps preexisting routes relatively intact, altering them only to insert a newly arrived customer service requests. The importance of the maintenance of the relative order of customers is discussed further in the section titled "Operational Challenges."

For simplicity, in the following, we will refer to customers who are known before the problem horizon as advance-request customers and those who become known during the problem horizon as immediate-request customers.

Myopic

Not surprisingly, the earliest work using insertion strategies ignored information about potential future requests. Examples of early work can be found in Refs 40 and 41. In both cases, insertion techniques are applied to insert newly arrived customers into preexisting routes, without any consideration of future requests. Larsen *et al.* [42] consider a variety of insertion procedures for dynamic routing and show that, when the objective is to minimize total expected distance traveled, a minimum cost insertion policy performs well. Reviews of myopic insertion and other early dynamic routing literature can be found in Refs 43–45.

Anticipatory

Anticipatory insertion improves upon myopic insertion by including known information

about the future, particularly in the determination of where and when to wait and in the construction of the initial tours of known customers. As an example, Thomas [24] considers the case where the locations of both advance- and immediate-request customers are known in advance. For an insertion-restricted solution with one immediate-request customer, the author identifies exactly when and where the vehicle should wait to maximize the probability of serving the immediate-request customer should it request service. The author then extrapolates this special case to a the general case and shows that, when the percentage of immediate-request customers is 25% or less, the extrapolation works well. As more of the customers become immediate, the waiting heuristic of Ref. 46 performs well.

Just as when and where to wait is important in the performance of an insertion-based solution, so is the initial tour into which immediate requests are to be inserted. Using information about potential future events in the construction of the tour can be advantageous. For instance, Manni [47] explores the value of using information about future requests in the construction of the initial tour. Interestingly, for the problem studied, Manni [47] finds that a good initial tour can be constructed using only the locations of all potential customers, without the need for any probabilistic information. Branke *et al.* [48] use Monte Carlo sampling of possible future events in order to derive initial tours in their application. Sampling techniques have played a prominent role in the methods discussed in the section titled “Anticipatory” under the section titled “Unrestricted Policies”. An example of other work in anticipatory insertion includes Ref. 49.

UNRESTRICTED POLICIES

Unrestricted dynamic routing solutions are those in which no structure is placed on the solution. For instance, consider the example given at the beginning of the previous section. A single vehicle serves a set of customers $\{1, 2, 3, 4, 5, 6, 7, 8\}$, the set $\{2, 3, 5, 6, 7\}$ of which have request service

and have been ordered $3 \rightarrow 5 \rightarrow 7 \rightarrow 2 \rightarrow 6$. Again assume that the next service request is customer 8. For the case in which the solution structure is unrestricted, no regard needs to be given to maintaining some semblance of the current order of the tour. Thus, in choosing to serve customer 8, the new sequence of customers might become $7 \rightarrow 5 \rightarrow 8 \rightarrow 3 \rightarrow 6 \rightarrow 2$. Further, in the case of unrestricted solutions, other than as an algorithmic feature, such as discussed in Ref. 50, there is no need to maintain any order of customers. At each time that a decision needs to be made, only the next decision, in our example the decision to visit customer 7, needs to be known.

Without the restrictions on the solution structure, unrestricted solution methodologies offer the possibility of better objective values than those found with the restricted solution structures. At the same time, solution-unrestricted methods can be applied across all problem classes.

Myopic

In the case of unrestricted solutions, the myopic approaches can be considered reactive in that requests for service are considered only when they occur. Initial work in this area focuses on what are known as *reoptimization* strategies. However, it is important to note that, despite the use of reoptimization in the nomenclature, the updated solution may in fact result from the application of a heuristic [51–55] or a hybrid exact and heuristic approach [56,57]. Regardless, the idea is that, after each new arrival, these reoptimization approaches treat the dynamic problem as a static one. Historically, these myopic approaches followed naturally from the extensive existing literature for static routing problems. However, these myopic, unrestricted methods differ from a priori methods in that the solution is updated, albeit without regard to dynamic information that may become known in the future, when dynamic information is learned. In recent work, Mitrović-Minić *et al.* [58] consider a reoptimization approach in which the objective is modified to implicitly account for future requests. This work builds on Ref. 46,

in which waiting rules were combined with reoptimization to improve performance.

In the past, the heuristic component was often necessary in order to find solutions in real time. In recent work, however, Chen and Xu [59] use an exact column-generation-based approach to update their solution as new service requests arrive. Thus, for some applications at least, it is possible to solve exactly the static problem and provide real-time decision making.

Anticipatory

As in the case of the other anticipatory solution methodologies, anticipatory, unrestricted solution methods incorporate information about future events into the solutions. In this class of solutions, exact solution methods are often limited to very small problems. For example, Thomas and White [60] demonstrate the value of including such information into the solution process, but demonstrates exact solutions for problems with only seven customers.

Similar to the transition from myopic insertion-restricted solutions to the anticipatory version, a natural approach for an anticipatory, unrestricted solution method is to combine the reoptimization of the section titled “Myopic” under the section titled “Unrestricted Policies” with an anticipatory waiting strategy. An example of such an approach is given in Ref. 50. Secomandi and Margot [61] also consider a reoptimization approach, but uses a restricted model of the stochastic problem in order to have a tractable problem that incorporates information about future events.

An interesting feature of many of the unrestricted solution methods is that they often employ of a priori, insertion-structured solutions, or both in order to solve subproblems. In this way, the unrestricted solution method can take advantage of existing research. For example, Erera and Daganzo [62] consider a two-phase real-time solution algorithm in which the first phase implements a traditional a priori scheme. Then, at a given point in time, all of the system information is assessed and a new solution is determined that reflects the known data. References 63 and 64 iteratively apply an

anticipatory a priori routing solution method in a heuristic algorithm known generally as a rollout algorithm [65]. The a priori solution method is applied iteratively at each decision point to update the solution as new information becomes known. Novoa and Storer [66] demonstrate the value of more sophisticated a priori routing than those used in Refs 63 and 64. Because many a priori routing problems need to be solved at every decision epoch, one of the difficulties encountered in the iterative use of a priori routing schemes is that they can be computationally expensive. Goodson *et al.* [67] explore this issue and in particular demonstrates a modification to traditional rollout algorithms, which while still requiring the iterative solution of a priori problems, greatly reduces the number that need to be solved.

In recent years, a class of solution methods has emerged that construct solutions by sampling future events. The intuition is that using sampling to help determine the next decision will allow the solution to better accommodate future events. An example of such an algorithm is given in Ref. 68. In the algorithm proposed in Ref. 68, the authors use sampling to construct a set of potential routes containing existing customers as well as possible future customers. Using a prespecified measure, the algorithm chooses a “best” routing plan from these sampled routes, and the next decision becomes the next customer specified in the chosen routing plan. An interesting feature of the algorithm proposed in Ref. 68 as well as related work such as Refs 69–73 is that the problems resulting from the sampling procedures are deterministic problems, like those that emerge in the approaches discussed in the section titled “Myopic” under the section titled “Unrestricted Policies”. As a result, these sample-based methods can take advantage of the existing literature for deterministic problems.

An emerging solution technique is known as *approximate dynamic programming* (ADP). A key feature of many ADP methods is the use of off-line simulations to estimate parameters of value-function approximations (see Ref. 74 for more on ADP). Theoretically, with the appropriate approximation, such

an ADP algorithm can return an optimal solution but without the constraint of needing to store the entire optimal policy. While there has been limited application of ADP to dynamic vehicle routing, the method has shown great promise in other dynamic decision making applications [7,8,11,12,14,15,18]. While ADP approaches may incorporate a priori- or insertion-restricted solutions such as in Refs 75 and 76, a straightforward ADP implementation, similar to what is found in Ref. 63, would not require knowledge of such solution approaches. Yet, three of the four ADP-based approaches [75–77] of which the author is aware all cite difficulty with the size of the action space that emerges in dynamic vehicle routing problems. Overcoming this challenge will be an important advance as a promising solution methodology is applied to dynamic vehicle routing.

A special class of dynamic routing problems is known as the *dynamic traveling repairman problem* (DTRP) or the *on-line traveling salesman problem* (OTSP). In both cases, a server (vehicle) seeks to serve customers who become known over time. The two differ in their objectives. In the DTRP, the objective is to minimize the expected amount of time that a customer waits after requesting service until being served. The OTSP seeks to minimize the expected routing cost. In contrast to much of the literature discussed previously, the research on the DTRP and OTSP focuses on characterizing asymptotically optimal policies or algorithms with provable asymptotic bounds on the difference between the on-line solution and the full information case (the competitive ratio). A recent survey can be found in Ref. 78. Examples of research in this area include Refs 79, 83.

OPERATIONAL CHALLENGES

As new technology and new methodologies make it possible to solve problems with complex objectives without restricting the structure of the solution, it is important to recognize the role that the structure of the solution plays in operational implementations of solutions. Wong [84] discusses the

fact that, in the package-express industry, it is important that drivers serve the same customers at about the same time every day. This “consistency” has two implications. One, it helps drivers to improve customer service by allowing them to build relationships with customers whom they see regularly. Second, drivers are more efficient the more familiar they are with the area in which they are driving. References 85–88 consider these issues by developing multiple period models that explicitly include consistency or more generally customer service measures. Further, a number of authors discuss that, while not explicitly modeling for customer service, a priori routing solutions can offer some of the desired customer service benefits [35]. At the same time, authors have shown that a priori routes can be competitive with the myopic, unrestricted approaches discussed previously [89,90]. Recently, Ghiani *et al.* [91] showed that an anticipatory, insertion-restricted solution can offer comparable performance to an anticipatory, unrestricted solution found through a state-of-the-art algorithm. More research is necessary to thoroughly understand whether or not the existing restricted solution structures can offer comparable value in terms of customer service or if there is value in developing models that explicitly model for it. The advantage of the restricted solution structures is that we have experience with and methodologies for solving them.

EDGEWORTH MARKET GAMES: PRICE-TAKING AND EFFICIENCY

PRABAL ROY CHOWDHURY
Indian Statistical Institute,
Delhi Center, Delhi, India

Consider M apple growers, each with an endowment of a unit of apples, and N bread makers, each with an endowment of b units of bread. In the absence of trade, the apple growers just consume their own apples, and the bread makers just consume their own bread. Most people prefer variety however, and presumably they would all prefer to consume some bread and some apple, rather than just one of these commodities. Edgeworth [1] examined the set of possible outcomes if trade now opens up in this economy. Using the notion of core (formalized later), Edgeworth provided a beautiful resolution of this question.

This question has continued to be one of the central ones in economics, generating a large literature which are often clubbed together under the title of Edgeworth market games. This literature models the trading process in an economy as a game played by utility maximizing agents. The solution concept used can be a cooperative one, or a noncooperative one.

Once technical issues of existence are resolved, the issues of interest are essentially twofold. A key aim of this literature is to provide a strategic foundation for price-taking behavior, a key element of perfect competition. By way of contrast, in the cooperative approach to trading, prices do not play a mediating role since agents can write binding contracts. Similarly, in the Arrow–Debreu–McKenzie (henceforth ADM) framework, while prices do play a mediating role, agents are *assumed* to be price takers. In contrast, the market game approach examines if price-taking emerges in the limit as the economy becomes large.

A related issue, which dates back to Ref. 1, is that of efficiency. Are the equilibrium outcomes Pareto efficient, in the sense there is no other possible outcome that is at least as good for all agents, and strictly better for some? This question is often examined in the context of large economies, where the issue of interest is whether, as the economy becomes large, the set of equilibrium outcomes converge to the set of Walrasian equilibria of the limit economy.

These are both complex issues however, and given the, by now, vast literature on market games, one must pick and choose. The focus of this article will be production economies in a partial equilibrium framework. While this does abstract from some of the intermarket interactions, doing so allows one to focus on the issue of price-taking behavior in a more transparent fashion. In such a framework, the issue of price taking, as well as efficiency reduce to a single one; that is, whether the equilibrium outcomes converge to the competitive one as the number of firms becomes large. Further, in a partial equilibrium framework one can examine these issues without going into measure theoretic complexities that are unavoidable in a general equilibrium framework.

Consequently, while we shall of course discuss other branches of the literature, these will be in lesser details. This in no way suggests that these are any less relevant, or important. Another reason is that there are existing surveys of these branches which do a brilliant job of surveying the literature.

The rest of the article is organized as follows. In the section titled “Exchange Economies: The Core” we discuss some of the key insights in the cooperative market games literature, before moving on, in the rest of the article, to the noncooperative approach. The section titled “Exchange Economies: The Trading Post Approach” discusses the trading post approach to market games, developed in several seminal articles by Shubik and Shapley. In the sections titled

“Production Economies: Cournot Competition Under Partial Equilibrium” and “Price Competition: Partial Equilibrium,” we turn our attention to market games with production, analyzing both the quantity, as well as the price setting framework in a partial equilibrium framework. The section titled “Quantity Competition with Free Entry: General Equilibrium” extends the free entry Cournot approach to a general equilibrium setting while the final section concludes this article.

EXCHANGE ECONOMIES: THE CORE

Consider an exchange economy (i.e., without production), with M apple traders (type 1), each with an endowment of a units of apples, and N bread traders (type 2), each with an endowment of b units of bread. The utility function of agent i is given by $u(a_i, b_i)$, where a_i and b_i denote the consumption of apples and bread respectively by the agent. The utility function is taken to be concave (weaker restrictions would suffice), capturing the fact that there is a love for variety. That the utility functions are taken to be symmetric is entirely for convenience.

Let x_i (respectively y_i) be the amount of apples (respectively bread) consumed by agent i . $(x, y) = (x_1, \dots, x_{M+N}, y_1, \dots, y_{M+N})$ constitutes an *allocation* vector for the economy if $x_i \geq 0$, $y_i \geq 0$, $\sum x_i = Ma$ and $\sum y_i = Nb$. The utility vector corresponding to an allocation will be called an imputation.

Definition. An allocation (x, y) is said to be a *core* allocation if there exists no subset of agents that can improve on it by trading only among themselves, that is all agents in the subset do at least as well compared to (x, y) , and at least one agent does strictly better.

We proceed by solving for the characteristic function of this game. Let $S = \{S_a, S_b\}$ denote a subset of agents consisting of s_a apple traders and s_b bread traders. Let $v(S)$ denote the maximal aggregate utility if agents in the set S trade with each other and

side-payments are allowed for. Thus

$$v(S) = \max_{x_1, \dots, x_{s_a+s_b}, y_1, \dots, y_{s_a+s_b}} \sum_{i=1}^{s_a+s_b} u(x_i, y_i), \quad (1)$$

where $\sum_{i=1}^{s_a+s_b} x_i = s_a a$ and $\sum_{i=1}^{s_a+s_b} y_i = s_b b$.

Since $u(a_i, b_i)$ is concave, $\sum_{i=1}^{s_a+s_b} u_i$ is maximized when the outcome is symmetric. Thus

$$v(S) = (s_a + s_b)u\left(\frac{s_a a}{s_a + s_b}, \frac{s_b b}{s_a + s_b}\right). \quad (2)$$

Remark 1. Note that for a bilateral exchange game, that is the $[1, 1]$ economy, $v(\{1\}) = (a, 0)$, $v(\{2\}) = u(0, b)$ and $v(\{1, 2\}) = 2u(a/2, b/2)$. Thus, the core imputation of this economy is

$$\{(u(a, 0) + \alpha c, u(0, b) + (1 - \alpha)c), 0 \leq \alpha \leq 1\}, \quad (3)$$

where $c = 2u(a/2, b/2) - u(a, 0) - u(0, b)$. The core for this game can be graphically represented using the Edgeworth box diagram and the contract curve in an entirely standard fashion.

$[1, N]$ -Economy

Consider a monopolist agent of type 1 facing many agents of type 2. In such a scenario can the monopolist charge very high prices? The following proposition suggests that the answer is in the affirmative.

Proposition 1. *The imputation $((N + 1)u\left(\frac{a}{N+1}, \frac{Nb}{N+1}\right) - Nu(0, b), u(0, b), \dots, u(0, b))$ lies in the core.*

Note that in this outcome, all bread traders are held down to their utility under autarchy, and all the gains from trade accrue to the monopolistic apple trader. Intuitively, the result follows since no group of agents that exclude the single apple trader can do any better since, given that none of them have any apples, the best that they can do is not to trade at all. This gives the apple trader an advantageous position. Further, while there could be other core allocations,

for N large, it can be shown that *any* core allocation must be arbitrarily close to the monopolistic outcome.

$[N, N]$ -Economy

For $i \notin S$, let $S^i = S \cup \{i\}$.

Definition. The economy is said to exhibit increasing returns to scale (IRS) (respectively decreasing returns to scale (DRS)) if for all S and $i, i \notin S$, $\frac{v(S^i)}{|S^i|} \geq \frac{v(S)}{|S|}$ (respectively $\frac{v(S^i)}{|S^i|} \leq \frac{v(S)}{|S|}$).

It can be shown that whether a core exists or not is intimately connected to whether the economy exhibits IRS, or DRS.

Proposition 2. *For the $[N, N]$ economy, a core exists, if the economy exhibits IRS, but not if it exhibits DRS.*

This is quite intuitive. With IRS, any group that plans to deviate from the grand coalition will have less surplus to distribute among its members, as its size is smaller compared to the grand coalition. Hence deviation from the grand coalition is not very attractive, and a core exists.

We shall not discuss the limit properties of such $[N, N]$ economies, as the economy becomes large. As discussed in the introduction, the issue is whether the set of core outcomes coincide with the Walrasian equilibria of the limit economy to which the $[N, N]$ economy converges. If so, then this implies that the set of Walrasian equilibria (i) has predictive power, and (ii) captures all outcomes arising out of the trading process. While any in-depth discussion of these issues must involve technical issues that are beyond the scope of this article, the results in the literature suggest that such convergence does take place (under the appropriate conditions). It is interesting that for large economies there is a close relation between the notion of core, which is a cooperative notion, and Walrasian equilibria, which is a noncooperative one. We refer the readers to Refs 2–4 for a detailed discussion of these issues.

EXCHANGE ECONOMIES: THE TRADING POST APPROACH

Much of the subsequent literature has, however, followed a noncooperative approach to modeling market games. One reason is that the cooperative approach with its emphasis on binding contracts is conceptually more attractive for small economies where the costs of writing such contracts are likely to be small. Further, the possibility of writing binding contracts imply that the process of price formation is implicit, thus abstracting from one of the key issues of interest. It should be mentioned though that for large economies there is a close connection between the core and Walrasian equilibria, which is (i) noncooperative, and (ii) does require a mediating role for prices.

We then discuss the trading post approach to market games first discussed in Refs 5 and 6. In contrast to the cooperative approach, prices play a central mediating role here. Further, prices emerge out of the strategic Cournotian interaction of the traders, with no need for either an Walrasian auctioneer, or any assumption of price-taking on the part of the agents. *Inter alia*, the trading post approach seeks to supplement the almost institution-free description of economies in the ADM tradition with explicit institutional details.

Consider an exchange economy with l commodities, and a set of consumers characterized by their preferences and initial endowments. There are l trading posts, one for each commodity, and some element called money. This money, may, or may not be fiat money (depending on the model). At each market j , an agent i decides on how much to offer of each commodity, denoted by y_i^j , and a bid of m_i^j for money. Let $y_i^j \leq w_i^j$, where w_i^j is the endowment of the i -th agent of the j -th commodity. Thus, the strategy for every agent consists of the pair (m_i^j, y_i^j) . The corresponding vector for all the agents can be written as (m, y) . In Ref. 5, for example, it is taken that agents have to supply all their endowments for trade, and the only strategic vector is the bid. Further, they impose the condition that $m_i^j \geq 0$, since they

consider a scenario where traders have to pay cash-in-advance.

The price emerges out of the sum total of all bids and offers, with the clearing price in market j being given by

$$p^j = \frac{\sum_i m_i^j}{\sum_i y_i^j}.$$

Note that the clearing rule for each market only depends on the bids and offers in that market. Given the prices, trade in each market can be solved for, with trader i obtaining $m_i^j/p^j - y_i^j$ of commodity j . Thus, unlike the ADM framework, there is no need for an auctioneer. Clearly the rules of the game are well defined (with some appropriate convention if prices are zero).

Next, consider a Cournot–Nash equilibrium of this game. A vector (m, y) is said to be feasible for agent i if the total amount of money pledged is less than equal to money obtained for this agent.

Definition. A feasible bid-offer vector (m, y) is a Cournot–Nash equilibrium if for all i , there does not exist any deviating offer-bid vector that is feasible for agent i , and is strictly preferred by this agent.

Reference 5 shows that under standard assumptions one can use the Kakutani fixed point theorem to prove existence of a Cournot–Nash equilibrium. Moreover, for the Ref. 5 model, an equilibrium with positive trade exists whenever the agents are sufficiently diverse [7]. In general of course a no-trading equilibrium always exists in this class of models.

Much of the subsequent literature has concentrated on the limit properties of Cournot–Nash equilibria, when the finite E_n economy with n agents approximates a continuum Aumann economy E . The literature shows that under the appropriate conditions, the set of Cournot–Nash equilibria of the trading post economy approximates the set of Walrasian equilibria of the limit economy as the economy becomes large.

We refer the readers to Ref. 8 for a detailed discussion of these issues. The Ref. 9 symposium issue on noncooperative foundations of

competitive equilibria bring together some important articles on this and related issues.

Remark 2. There are several related variations of the trading post models, such as Refs 10–13. Reference 14 provides an axiomatic treatment of this class of models, identifying the factors that lead to efficiency. Further, note that while we restrict attention to exchange models, the trading post model has been extended to allow for production [7]. This continues to be an active research area, with recent articles attempting to model issues of information transmission [15], default [16], and so on, using this approach.

PRODUCTION ECONOMIES: COURNOT COMPETITION UNDER PARTIAL EQUILIBRIUM

Continuing our discussion of noncooperative market games, we next turn to economies with production. In particular, we begin by discussing quantity competition under a partial equilibrium framework. This dates back to Cournot [17], who examined a game where two owners of mineral springs simultaneously decide on how much to supply in the market. Clearly, costs are zero. Even so, Cournot shows that the market outcome involves a strictly positive price, so that the equilibrium exhibits market power; that is, price is higher than marginal cost. This is clearly inefficient, even though competition does mitigate some of the inefficiencies associated with monopoly.

Efficiency is concerned with the divergence between the Cournot equilibrium price and the perfectly competitive price. The folk theorem of perfect competition suggests that, as the number of firms increases and/or the firm size becomes relatively small, the market price converges to the competitive one. This section examines the validity of the folk theorem in the quantity competition framework (the case of price competition will be taken up in the next section).

Recall that the Marshallian perfectly competitive model is based on U-shaped average cost functions (i.e., $c(q)/q$), with the competitive price being given by the minimum

point of the average cost function. Given the emphasis on the folk theorem, U-shaped average cost functions will play an important role in the analysis (for quantity, as well price competition). We shall allow for other forms of cost functions though.

Consider a model with n firms, all producing a homogeneous good. Let q_i denote the output of firm i , $Q = \sum_{i=1}^n q_i$ denote aggregate output, and Q_i denote the aggregate output of all firms but the i -th one. Let the inverse demand function be $f(Q)$ and the cost function of all firms be $c(q)$. Thus, the profit function of the i -th firm is given by

$$\pi(q_i, Q_i) = q_i f(Q) - c(q_i). \quad (4)$$

We make the following assumptions on the demand and the cost functions:

- A1.** The inverse demand function $f : [0, \infty) \rightarrow [0, \infty)$ is twice differentiable, intersects the quantity axis at $\hat{Q} > 0$, and is negatively sloped for all Q such that $\hat{Q} > Q > 0$.
- A2.** The cost function $c : [0, \infty) \rightarrow [0, \infty)$ is twice differentiable (except possibly at $q = 0$), increasing in q , and $c(0) = 0$.
- A3.** The Hahn conditions hold, that is $\forall q, Q$, where $0 \leq q \leq Q$, (i) $f'(Q) - c''(q) < 0$, and (ii) $f''(Q) - q_i f'''(Q) < 0$.

Consider the Cournot game where all the firms simultaneously decide on their quantity q_i , where $q_i \in [0, \infty)$. We look for Nash equilibria of this game in pure strategies.

Proposition 3. *Under A1–A3, the Cournot game has an equilibrium in pure strategies.*

Given A1–A3, $\pi(q_1, \dots, q_n)$ is strictly concave in q_i and continuous in $(q_1, \dots, q_n)$. Further, the strategy set for all firms can be effectively restricted to $[0, \hat{Q}]$ so that it is compact. The preceding proposition then follows from the Debreu fixed-point theorem.

While uniqueness is of some interest, it is not central to our concerns, and we just refer the interested reader to Ref. 18 instead. We then concentrate on studying the limit properties of Cournot equilibria. We shall

consider two different approaches, one with exogenous, and the other with free entry.

As the formal analysis (to follow) demonstrates, the analysis depends on the relative efficacy of two forms of competition, actual and potential, in generating efficiency. By *actual competition* we mean the number of active firms in an industry, since these firms exert a direct competitive effect on the other firms in the industry. *Potential competition* refers to the fact that even inactive firms create a competitive pressure in that if the market price is too high, then such firms can enter and have a positive profit.

We shall demonstrate that the strength of actual competition depends on the shape of the average cost function, in particular whether it is increasing, or U-shaped. It turns out that actual competition is sufficient to generate the competitive price as long as the average cost function is increasing, but not if it is U-shaped. When average costs are U-shaped, we find that the competitive price obtains if potential competition is strong, that is there is free entry of firms, and firm size vis-a-vis market size is small.

Exogenous Entry

Under the exogenous entry approach, firm size vis-a-vis market size is taken to be given, and one examines the limiting properties of equilibrium prices as the number of firms, which is exogenously given, taken to infinity. This approach was pioneered by Okuguchi [19] and Ruffin [20], among others.

To begin with, note that if there are fixed costs of production, so that $c(0) > 0$, then the number of active firms cannot be arbitrarily large, since some firms will be making losses otherwise. While this is an important caveat, it is well understood and in the rest of the subsection we therefore concentrate on the case where there are no fixed costs, so that cost functions are continuous at zero.

Proposition 4. *Let A1–A3 hold, the cost function be continuous at $q = 0$ and further assume that for all n a unique, symmetric, and interior equilibrium exists.*

(a) *If the average cost is increasing in q , then for n large the Cournot equilibrium price converges to the competitive price, that is $c'(0)$.*

(b) If the average cost has the classical U-shape, then for n large, the Cournot equilibrium price does not converge to the competitive price.

Proof. We begin by arguing that for n large, the equilibrium price converges to $c'(0)$. Let $q(n)$ denote the unique symmetric equilibrium price. Given that the demand function intersects the quantity axis, $\lim_{n \rightarrow \infty} q(n) = 0$. Thus, from the first order condition and symmetry

$$\begin{aligned} \lim_{n \rightarrow \infty} f(nq(n)) \\ = \lim_{n \rightarrow \infty} [-q(n)f'(nq(n)) + c'(q)] = c'(0). \end{aligned} \quad (5)$$

Finally, note that for increasing average costs, the competitive price is in fact $c'(0)$. Whereas for U-shaped average costs, the competitive price is the minimum point of the average cost curve, which is less than the competitive price.

Proposition 4 has interesting efficiency implications. It shows that while the folk theorem goes through under the exogenous entry approach whenever the average cost is increasing, it fails whenever it is U-shaped. Under the exogenous entry approach therefore, the nature of technology, that is firm size, has an important bearing on the limiting outcome. Let firm size be formalized by the minimum efficient scale. Thus, efficiency obtains when the minimum efficient scale is zero (i.e., average costs are increasing), but not otherwise. Interestingly, a firm size close to zero does not ensure a limit equilibrium price close to zero (since a firm size close to zero is consistent with $c'(0)$ being bounded away from the competitive price).

Why do the competitive outcome obtains even in the absence of free entry (i.e., potential competition) whenever average cost is increasing? Intuitively, with increasing average costs, the minimum efficient scale is zero (recall that the competitive price corresponds to the average cost at the efficient size). Thus as actual competition increases, competition drives the output level of every firm towards the efficient scale, so that price goes towards

the competitive price. With U-shaped average costs however, an increase in average costs drives the output level of the firms away from the minimum efficient scale.

Free Entry

Novshek [21] argues that the notion of perfect competition itself incorporates notions of (i) free entry, and (ii) firm size being small. It is a combination of these two elements that generates the competitive pressure under perfect competition, leading to efficiency. Thus any reasonable oligopoly foundation of perfect competition needs to start with a model that allows for free entry and then examine limiting behavior when firm size becomes small vis-a-vis market size. Consequently, it may be argued that is not very surprising that the folk theorem fails under the exogenous entry approach, which allows for neither of these aspects.

Consider a market with a countably infinite number of firms and an inverse demand function $f(Q)$ satisfy A1. The firms are symmetric and have the cost function $c(q)$, where $c(q)$ satisfies A2 and

A4. The average cost function $AC : (0, \infty) \rightarrow (0, \infty)$ is continuous on $(0, \infty)$, strictly U-shaped, and achieves a unique minimum at $q = 1$. Moreover, there exists q such that $f(q) > AC(q)$.

Note that the cost function need not be continuous at $q = 0$, thus allowing for fixed costs.

We begin by defining the notion of a free-entry Cournot equilibrium.

Definition. $(q_1^*, \dots, q_n^*)$ constitutes a free-entry Nash equilibrium with n active firms if the following two conditions are satisfied:

- (a) *Cournot Equilibrium.* $(q_1^*, \dots, q_n^*)$ constitutes the equilibrium of an n -firm Cournot model without free entry, that is $q_i^* f(Q^*) - c(q_i^*) \geq q_i f(Q_i^* + q_i) - c(q_i)$, for all active firm i and $\forall q_i \geq 0$.
- (b) *Free Entry.* No inactive firm can enter and make a strictly positive profit, i.e. there does not exist $q' > 0$ such that $q' f(Q^* + q') - c(q') > 0$.

We examine the limit properties of free-entry equilibrium as firm size becomes small. We therefore, next turn to the task of formalizing a reduction in firm size. Recall that firm size is captured through the minimum efficient scale. That is, the output level where AC is minimized. We next define a family of cost functions parametrized by α defined as

$$AC_\alpha(q) = AC\left(\frac{q}{\alpha}\right). \quad (6)$$

Note that a firm with a cost function $AC_\alpha(q)$ achieves a minimum average cost at $q = \alpha$ and thus, has a firm size of α . Further, for any such α , the competitive price equals $AC_\alpha(\alpha) = AC(1)$. Finally, let X denote the competitive output, that is $f(X) = AC(1)$.

Proposition 5 below shows that for α small, the equilibrium output is arbitrarily close to the competitive one. Thus the folk theorem holds in this case. Interestingly, the result holds even if there are fixed costs, or if the average cost is U-shaped.

Proposition 5. *Let A1, A2, and A4 hold. For α small, a free-entry Cournot equilibrium exists. Moreover, the equilibrium output lies in $[X - \alpha, X]$.*

Proof. For the existence proof we refer the readers to Ref. 21. Next suppose that the aggregate equilibrium output, $Q^* > X$. But then $f(Q^*) < f(X)$, where recall that $f(X)$ is the minimum average cost. But then all active firms must be making a loss. Next, suppose that $Q^* < X - \alpha$, so that $f(Q^* + \alpha) > f(X)$. But then an inactive firm can enter, supply exactly α and make a positive profit.

Intuitively, the result is driven by the presence of free entry. With free entry, whenever prices are too high, inactive firms can always enter and produce at the minimum efficient scale. Since the price level is high to begin with, even with an increase in the output level, the resultant price is going to be higher than the average cost of the new entrant so that such a firm has an incentive to enter. This consideration provides a bound on how far the equilibrium price can

exceed the competitive price, with the bound approaching the competitive price as the efficient scale becomes smaller.

We note the fact that the inverse demand function is negatively sloped plays an important role here as this ensures that it sends the right signal for entry, ensuring that entry occurs precisely when prices are high. In order to emphasize this point, consider an inverse demand function which is not necessarily negatively sloped. In particular, let there be three aggregate output levels Q, Q', Q'' , such that $Q < Q' < Q''$, that generate a market price of $AC(1)$. Further let the demand function be negatively sloped at Q , and Q'' , but positively sloped at Q' . Mimicking Proposition 4, it is straightforward to show that for α small, no output in $[Q', Q' + \alpha]$ can be sustained as a free-entry equilibrium. This is because at any such output level, an inactive firm will have an incentive to enter and make a positive profit. As we shall see later, the critical condition that ensures efficiency under Cournot competition in a general equilibrium framework is something similar, that is some generalized demand function be negatively sloped.

PRICE COMPETITION: PARTIAL EQUILIBRIUM

Bertrand [22] criticized Cournot, arguing that firms actually compete over prices, and not quantities. While it is known that there are close connections between models of quantity and price competition, examining the limit properties of equilibria under price competition is of interest. Price competition has the further appeal that prices emerge directly out of the strategic interactions of the agents.

Next, we therefore examine market games where firms compete over prices, rather than quantities, with an aim to analyzing the limit properties of such equilibria. As we shall see, there are some differences in results between price and quantity competition. Under price competition we shall examine two different frameworks, the Bertrand–Chamberlin and the Bertrand–Edgeworth framework,

showing that the limit properties of the equilibrium prices are critically dependent on the underlying framework.

Bertrand–Chamberlin Framework

Under this framework, first developed by Chamberlin [23], firms have to supply the whole of the demand coming to them. This may be because of either government regulations, or reputational effects. Reference 18, for example, suggests that in many public utilities like electricity and telephone in the United States, such restrictions are in place. Under the “common carrier” regulation, firms are required to supply all demand at the set prices. Alternatively, under some sealed bid auctions, firms have to supply all demand that come to them in case they win the auction. Such costs are routinely adopted in operations research [24,25].

We now proceed with a description of the model. The analysis in this subsection follows [26]: Let there be n firms with the market demand function $F(p)$ satisfying

- A5.** $F : [0, \infty) \rightarrow [0, \infty)$. Further, $F(p)$ is continuous, intersects the price axes at $\hat{p}$, and is strictly decreasing on $[0, \hat{p})$.

Given the Chamberlin assumption, the residual demand facing firm i , if the announced price vector is $(p_1, p_2, \dots, p_n)$ is

$$D_i(p_1, \dots, p_i, \dots, p_n) = \begin{cases} 0, & \text{if } p_i > p_j, \text{ for some } j, \\ \frac{F(p_i)}{m}, & \text{if } p_i \leq p_j, \forall j, \text{ and } \#(l : p_l = p_i) = m. \end{cases}$$

Note that the market is equally shared by all firms that charge the lowest prices. All other firms have no demand. Thus, the profit of the i -th firm when the average cost function is $AC(q)$ is

$$\begin{aligned} \pi_i(p_1, \dots, p_n) &= (p_i - AC(D_i(p_1, \dots, p_n)))D_i(p_1, \dots, p_n). \end{aligned} \quad (7)$$

We look for pure-strategy Nash equilibria of the game where all firms simultaneously announce their prices.

We begin by considering the case where cost functions are linear. Whenever there

are at least two firms, it turns out that price equals marginal cost equals average costs, so that there are no supernormal profits. Hence the competitive equilibrium obtains even with only two firms—the Bertrand paradox! The paradox arises because intuition suggests that with only a few firms, the market price should be greater than the competitive one (however, see Ref. 27).

Proposition 6. *Let the cost function be $cq_i \forall i$, and A5 hold. The unique pure-strategy equilibrium involves all firms charging the same price c .*

Given the Bertrand paradox we consider strictly convex costs, in particular we allow for U-shaped average cost functions. Let $c(q)$ denote the common cost function of all firms where $c(q)$ satisfies A2. Further, let the average cost function $AC(q)$ satisfy

- A6.** The average cost function $AC : (0, \infty) \rightarrow (0, \infty)$ is continuous on $(0, \infty)$. There exists $\tilde{q}$ such that $AC(q)$ is decreasing for $q \leq \tilde{q}$, and increasing for $q \geq \tilde{q}$. Moreover, there exists p such that $p > AC(F(p))$.

We need some more definitions (these are well defined under our assumptions).

$$b = \lim_{q \rightarrow 0} AC(q).$$

$$c^* = \inf_q AC(q).$$

$d(1)$ is the minimum p such that $AC(f(p)) = p$. A monopoly firm charging some price p , makes a loss whenever $p < d(1)$. Whereas for any $p > d(1)$, there exists some $p' < p$, such that charging p' yields a positive profit to a monopoly firm.

Exogenous Entry. Recall that under the exogenous approach firm size relative to market size is taken as given, and one then examines the effect of an increase in the number of firms on the outcome. One therefore examines the limit equilibrium set which comprises of all prices that can be obtained as the limit of a sequence of equilibrium prices as the number of active firms becomes large.

We thus examine the properties of the set S , where S is the set of all prices p such

that for all sufficiently large n , there is some equilibrium where all firms are active and the equilibrium price is arbitrarily close to p .

Proposition 7. *Let A2, A5, and A6 hold, and let the Chamberlin assumption hold, i.e. firms supply all demand. The limit equilibrium set under exogenous entry $S = [b, d(1)]$ whenever $b \leq d(1)$. Otherwise, S is empty.*

The result is quite intuitive. Consider any price $p < b$. Can such a p be an element of the limit equilibrium set? Then, as the number of active firms increases, the output of all firms becomes small, so that average cost goes to b . But this implies that the firms make losses. Next, consider any price $p > d(1)$. For n large, the profit of the firms goes to zero, whereas by undercutting, the firms get a profit that is bounded away from zero for all n . Finally, consider some $b < p < d(1)$. For n large the average cost is close to b , so that firms make positive profits with $b > p$. Moreover, since $p < d(1)$, undercutting is not profitable.

Thus, while the competitive price is an element of the limit equilibrium set, there are other elements also. Intuitively, multiple equilibria obtain since under the Chamberlin assumption, any under-cutting firm will have to supply the whole of the demand coming to it, which given that cost functions are convex, is very costly. Reference 28 examines a model of Bertrand–Chamberlin competition that allows for limited collusion among the firms. They find that with symmetric firms, the coalition-proof Nash equilibrium converges to the competitive price when the number of firms becomes large.

Comparing with the results under Cournot competition (Proposition 4), with increasing average costs, the folk theorem holds under Cournot competition, but fails under price competition. Whereas for U-shaped average costs, the folk theorem fails under both approaches.

Free Entry. We then examine free-entry equilibrium under price competition, with free entry being modeled as the presence of inactive firms in equilibrium. Under this approach, one solves for the limit equilibrium set T , comprising all prices that

can be sustained as the limit of a sequence of free entry equilibrium prices as firm size becomes small relative to market size. We are thus interested in the set T , where T is the set of all prices p such that if the demand sector is large enough then there is an equilibrium involving both active and inactive firms such that the equilibrium price is arbitrarily close to p . Consider an r -economy, where the demand sector is replicated r -fold.

We need one more piece of notation. Let $d^* = \lim_{r \rightarrow \infty} d(r)$, where $d(r)$ solves $AC(rf(p)) = p$.

In Proposition 8 below we characterize the set T for U-shaped average cost functions.

Proposition 8. *Let A2, A5, and A6 hold, the average cost be U-shaped, and firms supply all demand. Then the limit equilibrium set under free entry $T = [c^*, \min\{b, d^*\}]$.*

While the complete argument can be found in Ref. 26, here we just consider p such that $c^* < p < \min\{b, d^*\}$. Why does such a p belong to the limit equilibrium set? This follows since for any sufficiently large r -economy, undercutting p will lead to a loss. For r large enough, in case of undercutting, the undercutting firm must supply a demand of at least $rf(p)$. For r large, the corresponding average cost will be close to $\min\{b, d^*\}$. Since this is greater than p , the undercutting firm will make a loss.

It is interesting to compare the results with Proposition 6. Note that in the presence of free entry, the limit equilibrium set shifts to the left, suggesting that free entry leads to a fall in prices. Thus free entry does play a role in generating outcomes close to the competitive one. There are other prices however that can be sustained in equilibrium. Intuitively, this is because with the Chamberlin assumption and convex costs, undercutting is very costly, so that even free entry and small firm size is not sufficient to guarantee that the competitive price obtains.

Recall that under Cournot equilibrium, for U-shaped average costs the folk theorem holds under the free-entry approach (Proposition 5). Thus under the free entry approach, the folk theorem fails under

price competition, but goes through under Cournot competition. This shows that under the Chamberlin assumption, free entry is not sufficient to restore efficiency. This is because with convex costs and the Chamberlin assumption, either undercutting, or even matching the existing market price can be very costly for an inactive firm, thus weakening the competitive impact of free entry.

Bertrand–Edgeworth Competition

We then examine a price-setting game where the voluntary trading constraint holds; that is, firms are free to supply less than the demand coming to them. This implies of course that no firm will supply beyond the point such that price equals marginal cost. Such a framework makes sense when there is no cost of turning customers away.

Note that the voluntary trading constraint implies that firms charging higher prices may get a residual demand if the lower priced firms are not meeting the demand coming to them. We shall restrict attention to the cases where the residual demand is either proportional, or parallel.

For the case where $n = 2$, let firm 1 charge $p_1 > p_2$ and firm 2 supply $q_2 < d(p_2)$. Then the residual demand coming to firm 1 is $\max\{0, d(p_1) - q_2\}$ if the demand is parallel, and $d(p_1) \frac{d(p_2) - q_2}{d(p_2)}$ if the demand is proportional. For a description for the general case we refer the readers to Ref. 25.

With convex costs we have nonexistence of equilibria in pure strategies, the well-known Edgeworth paradox [29].

Proposition 9. *Let $n = 2$ and both firms have a strictly convex cost function $C(q)$. Then, no pure-strategy Nash equilibrium exists for either the parallel, or the proportional residual demand function.*

The result is intuitive. For any market price higher than the competitive price, one of the firms will have an incentive to undercut. If, however, both firms charge the competitive price, then increasing prices slightly is profitable, since the price effect dominates the quantity effect which has a second-order impact (as price equals

marginal cost at the competitive price). In fact, Ref. 30 shows that even with linear costs, the Edgeworth paradox obtains if firms produce to stock, that is decide on their prices and quantities simultaneously.

Given the Edgeworth paradox, the literature has pursued several different approaches. Reference 31 examines conditions under which Bertrand–Edgeworth games will have existence.

Capacity-Constrained Linear Costs. One route has been to examine cost functions which are linear, but have a capacity constraint. For such models, Refs 32 and 33 both find that the equilibrium converges in distribution to the competitive price. However, while Ref. 33 shows that for the parallel rationing rule there is convergence in the support as well, for the proportional rationing rule Ref. 32 finds that in general the monopolistic price always belongs to the support of equilibrium prices. For the parallel rationing rule Ref. 34 shows that iterated elimination of dominated strategies yields prices close to the competitive one.

Clearly, both Refs 32 and 33 adopt the exogenous entry approach. Further, both authors examine limiting procedures where the capacity level, which can be taken to be a proxy for firm size, is taken to zero. Thus with exogenous entry, capacity constraints, and a limiting procedure that takes firm size to zero, the folk theorem goes through under price competition, at least in the sense of convergence in distribution. Recalling Proposition 4(a), we find that these results are similar in flavour to that under Cournot competition with increasing average costs. In both cases the point seems to be that whenever the efficient firm scale is zero, actual competition is enough to generate efficiency.

Note however that while we are interpreting these models as one of Bertrand–Edgeworth competition, these might very well be interpreted as one with Bertrand–Chamberlin competition where the Chamberlin constraint takes the weaker form that firms must supply till the maximum of its capacity, and the demand coming to it. This is because with linear costs, if it

is profitable to supply any positive amount, then it must be optimal to supply till capacity.

Grid Pricing

Reference 35 examines a model with grid-pricing and smoothly convex cost functions, where the firms simultaneously decide on both their prices and quantities. Further, in case of a tie in the lowest prices, suppose that beyond a point the residual demand coming to any firm is insensitive to the quantity supply by this firm. Then for any grid size, if the number of firms (n) is large enough, then there is a unique Nash equilibrium where the equilibrium price is within a grid-unit of the competitive price. Moreover, the output levels of individual firms become vanishingly small as n becomes very large, and the aggregate output is close to the competitive one.

The intuition is as follows. Suppose all firms charge the lowest possible price in the grid that is greater than the marginal cost at zero. Then for n large, it is residual demand rather than marginal cost which determines firm supply. In that case price would not equal marginal cost, and firms may have no incentive to increase their price levels.

Interestingly, in case firms tied at the lowest price can manipulate the residual demand coming to them by increasing their output level, the aggregate equilibrium output may be ill-behaved. While the competitive price (modulo the grid) still turns out to be an equilibrium, the limiting value of the aggregate output diverges to infinity if $c'(0) = 0$ and n is taken to infinity. This is because in this case the costs of manipulating residual demand via quantity is small, so that all firms have an incentive to produce too much.

Remark 3. Reference 36 examines a model with decreasing average costs, showing that for small enough grid size the equilibrium price converges to the contestable one when the firms are symmetric. If the firms are asymmetric however, then Ref. 37 shows that the convergence is to the limit-pricing one.

Remark 4. Reference 29 also allows for convex costs, examining the ϵ -Nash

equilibria of Bertrand–Edgeworth equilibria. For parallel rationing rules, Ref. 29 shows that an ϵ -Nash equilibria exists when the market is replicated, and moreover the ϵ -equilibria converge to the competitive one. In Ref. 29, the replication process involves replicating market demand, which involves making firm size relatively small, as well as increasing the number of firms.

Remark 5. An alternate approach is to examine the case when products are differentiated [38]. This again is a vast literature, and for lack of space will not be discussed here.

Thus, the preceding discussion suggests that for Bertrand–Edgeworth competition and the exogenous entry approach, the equilibrium outcome approximates the competitive one in the limit whenever (i) either the cost functions are linear with capacity constraints and the limit procedure involves taking firm size to zero, or (ii) there is grid-pricing and the tie-breaking rule is not too manipulable. For the proportional rationing rule and capacity constraints, the convergence is however in distribution, and not in the support. Further, under grid-pricing and strongly manipulable tie-breaking rules, while the equilibrium price converges to the competitive one, the aggregate equilibrium output may not.

QUANTITY COMPETITION WITH FREE ENTRY: GENERAL EQUILIBRIUM

This section is based on Refs 39 and 40. Proposition 5 earlier shows that the key to obtaining efficiency under partial equilibrium Cournot competition is to allow for free entry. Extending this intuition to a general equilibrium framework, one obtains what Novshek and Sonnenschein call the Cournot–ADM–Marshallian synthesis. This is of importance for several reasons:

1. This explains price-taking behavior, rather than postulate it as under the Arrow–Debreu–McKenzie framework.

2. It allows a role for dynamics via entry and exit of firms.
3. It allows for intermarket interactions, not allowed for in a partial equilibrium framework.
4. It allows us to reexamine the fundamental welfare theorems in a framework that allows for entry and exit of firms, and obtains price-taking behaviour in the limit.

Consider a general equilibrium economy where the firm sector consists of countably infinite number of firms and free entry, with each firm's production possibility being given by two components: the origin (which allows for free entry) and a compact, strictly convex component, which moreover is bounded away from zero. Thus, unlike the ADM framework, the production set is nonconvex. Moreover, it provides a natural analogue of the U-shaped average cost under partial equilibrium (given that the second component is bounded away from zero). Finally, let the second component of the production set be parametrized by α , so that a smaller α naturally implies a scaling down and captures the idea of smaller-sized firms. The central point is that as α goes to zero, the aggregate production set converges to a convex technology.

The consumers are treated as price-takers, with each consumer i owning a fraction θ_i of all firms and having an initial wealth level of w_i . Thus, given a price vector p , each consumer has an income level of $p \cdot w_i + \theta_i p \cdot y$, where y denotes net aggregate production. Let the demand function of this consumer be $D_i(p, p \cdot w_i + \theta_i p \cdot y)$.

Define an inverse demand selection $F(y)$ as a price vector that clears markets given the output and entry decisions

$$\sum_i D_i(p, p \cdot w_i + \theta_i p \cdot y) - \sum_i w_i = y. \quad (8)$$

Note that $F(y)$ is the general equilibrium equivalent of the partial equilibrium inverse demand function. Further, given $F(y)$, it is straightforward to extend the notion of free-entry Cournot equilibrium to the general equilibrium framework for an economy with firm size α , denoted $E(\alpha)$.

References 39 and 40 show that under a condition they call DSD on the generalized inverse demand $F(y)$, analogs of the fundamental welfare theorems extend to this set up. They say that the aggregate inverse demand $F(y)$ satisfies the DSD condition if, for α small, entry by a new firm reduces profits after changes in all prices are accounted for. Intuitively, it is clear why DSD is required. Consider an equilibrium of the limit economy that does not satisfy DSD. Then for any aggregate output close to but less than this output, an inactive firm will have an incentive to enter since, by doing so, it can earn a positive profit.

Thus Refs 39 and 40 provide a synthesis of the Cournot–Marshall approach with the ADM framework. In so doing, they provided a foundation for the price-taking assumption, as well as the perfectly competitive model. They also show that the fundamental welfare theorems go through in this framework, and also enhances these by showing that (i) competition leads to the optimal number of firms, (ii) emphasizes the role of wealth distribution on price signals, and (iii) does not impose convexity of the aggregate production function.

Remark 6. While the analysis in this section (as well as the earlier two sections) focus on the case with nonconvex technologies, Refs 41 and 42 examine an alternative framework where the aggregate production set is assumed to be convex and the number of agents is exogenously given. We refer the readers to Ref. 8 for a discussion of this approach.

CONCLUSION

The market game literature contributes a lot to our understanding of several aspects of multilateral trading. The cooperative literature shows that if binding contracts are not too costly, then, for large markets, trading outcomes converge to the Walrasian equilibrium. The noncooperative approach focuses on the role of price formation. The trading post models confirm the intuition that even

when agents behave noncooperatively, the invisible hand of Adam Smith continues to operate. The partial equilibrium oligopoly models clarify the role of firm interaction in generating efficiency. Under quantity competition, one key insight is that unless average costs are increasing, efficiency, that is convergence to the competitive price, requires not only actual competition, but both free entry as well as firm sizes being small. Under price competition, some new insights emerge. Whether the voluntary trading constraint holds or not, turns out to be of importance. When the voluntary trading constraint holds, we find that the perfectly competitive price obtains in the limit (subject to some caveats). The results however, are quite different in case the firms have to supply all the demand. In this case, even free entry and small firm size is not enough to guarantee the efficient outcome. Finally, the free-entry Cournot model with general equilibrium provides a synthesis of the Marshallian model with the Arrow–Debreu–McKenzie framework. *Inter alia*, it provides a foundation for price-taking behavior, and augments the fundamental welfare theorems with new insights.

INTRODUCTION

Many combinatorial optimization problems especially those found in industry and government are either computationally intractable by their nature, or sufficiently large so as to preclude the use of exact algorithms. In such cases, heuristic methods are usually employed to find good, but not necessarily guaranteed optimal, solutions. The effectiveness of these methods depends upon their ability to adapt to a particular realization, avoid entrapment at local optima, and exploit the basic structure of the problem. Building on these notions, various heuristic search techniques have been developed that have demonstrably improved our ability to obtain good solutions to difficult combinatorial optimization problems. The most promising of such techniques include simulated annealing [1], tabu search [2–4], genetic algorithms [5], variable neighborhood search (VNS) [6], and GRASP (greedy randomized adaptive search procedure) [7,8].

A GRASP is a multistart or iterative process [9], in which each GRASP iteration consists of two phases, a construction phase, in which a feasible solution is produced, and a local search phase, in which a local optimum in the neighborhood of the constructed solution is sought. The best overall solution is retained as the result.

In the GRASP construction phase, starting from an empty solution at each iteration

a new element is added to the partial solution in a greedy, randomized, and adaptive fashion. Let C be the set of element candidates to be inserted in the solution under construction. The greedy and random construction is blended either by using greediness to build a restricted candidate list ($RCL \subseteq C$) of the current best ranked elements and randomness to select an element from the list, or by using randomness to build the list and greediness for selection. Candidate elements $e \in C$ are sorted according to their greedy function value $g(e)$. In a *cardinality-based construction*, the RCL is made up by the k top-ranked elements. In a *value-based construction*, the RCL consists of the elements in the set $\{e \in C : g_m \leq g(e) \leq g_m + \alpha(g_M - g_m)\}$, where $g_m = \min\{g(e) : e \in C\}$, $g_M = \max\{g(e) : e \in C\}$, and $\alpha \in [0, 1]$. Since the best value for α is often difficult to determine, it is often assigned a random value for each GRASP iteration.

An especially appealing characteristic of GRASP is the ease with which it can be implemented. Few parameters need to be set and tuned, and therefore development can focus on implementing efficient data structures to assure quick GRASP iterations.

In this article, we briefly review the literature of operations research and computer science applications of GRASP as well as industrial applications. We cover applications in scheduling, routing and transportation, logic and partitioning, graph theory, location and assignment, manufacturing, telecommunications and power systems. The article concludes with a section on applications in biology and related fields.

SCHEDULING

GRASP has been applied to a wide variety of scheduling problems. One of the pioneering works illustrating a GRASP for scheduling is the paper of Bard and Feo [10], which appeared in 1989. This paper describes a method for efficiently sequencing cutting operations associated with the manufacture

of discrete parts. The problem is first modeled as an integer program and then relaxed via Lagrangian relaxation into a min-cut problem on a bipartite network. To obtain lower bounds, a max-flow algorithm is applied and the corresponding solution is input to a GRASP. Feo *et al.* [11] proposed a GRASP for single machine scheduling with sequence dependent setup costs and linear delay penalties. Here, the greedy function of the GRASP construction phase proposed is made up of two components: the switch-over cost and the opportunity cost associated with not inserting a specific job in the next position and instead, inserting it after half of the unscheduled jobs have been scheduled. This greedy function tends to lead to a balance between the natural order and nearest neighbor approaches. The local search uses 2-exchange, insertion exchange, and a combination of the two. Another interesting application of GRASP for solving real-world scheduling problems is due to Xu and Chiu [12], who proposed an effective heuristic procedure for a field technician scheduling problem, where the objective is to assign a set of jobs at different locations with time windows to technicians with different job skills. Several heuristics, including a GRASP, are designed and tested for solving the problem. The greedy choice is to select jobs with the highest unit weight. The local search implements four different moves, among them the 2-exchange and a swap that exchanges an assigned job with another job unassigned under the candidate schedule.

Several hybrid approaches have been also proposed that combine GRASP with other techniques, including tabu search for the school timetabling problem [13], path relinking for the job shop scheduling [14] and branch-and-bound (B&B) for the job shop scheduling [15], and a scheduling problem with nonrelated parallel machines and sequence-dependent setup times [16], where at each GRASP iteration, the greedy criterion adopted to build a feasible solution consists in sorting the jobs in a nondecreasing order using the due date and then assigning each job to the machine that can finish it first. In 2008, two further

interesting hybrid techniques had been proposed. Alvarez-Valdes *et al.* [17], describe a reactive GRASP for a strip-packing problem, while they, in [18], propose several heuristic algorithms based on GRASP and path relinking for project scheduling under partially renewable resources. In this case, the greedy selection is based on a priority rule and the improvement phase consists of two steps. First, it identifies the activities whose completion times must be reduced in order to have a new solution with the shortest makespan and labeling these activities as critical. Second, it moves critical activities in such a way that the resulting sequence is feasible according to precedence and resource constraints. In particular, the authors have designed two types of moves: (i) in a simple move, only a critical activity is moved, leaving the remaining activities unchanged; (ii) in a double move, noncritical activities are moved to make the move of a critical activity possible.

ROUTING AND TRANSPORTATION

GRASP has been applied to several vehicle, aircraft, telecommunications, and inventory routing problems. In 1995, Kontoravdis and Bard [19] proposed a GRASP for minimizing the fleet size of temporarily constrained vehicle routing problems with two types of service. The greedy function of the construction phase takes into account both the overall minimum insertion cost and the penalty cost. Local search is applied to the best solution found every five iterations of the first phase, rather than to each feasible solution. In 1998, a modified and improved version of this GRASP was extended for the inventory routing problem with satellite facilities by Bard *et al.* [20], who proposed a methodology that decomposes the problem over the planning horizon, and then solves daily rather than multiday vehicle routing problems.

In 2002, Carreto and Baker [21] investigated the incorporation of interactive tools into heuristic algorithms and proposed a GRASP interactive approach to the vehicle routing problem with backhauls. A GRASP

has been used in the routes construction and improvement phase. The construction phase is implemented using a clustering heuristic that constructs the routes by clustering the remaining customers according to the vehicles defined by seeds while applying the 3-opt heuristic to reduce the total distance traveled by each vehicle. The greedy function takes into account routes with smallest insertion cost and customers with biggest difference between the smallest and the second smallest insertion costs and smallest number of routes they can traverse.

Corberán *et al.* [22] proposed a pure GRASP for the mixed Chinese postman problem, while a hybrid GRASP with tabu search has been proposed by Li *et al.* [23] for vehicle routing with both time window and limited number of vehicles. To efficiently solve the rural postman problem, de la Peña [24] published, in 2004, an interesting case study to compare several metaheuristics approaches, including a simulated annealing, a GRASP, and a genetic algorithm.

GRASP has been used also to find approximate solutions of problems in air, rail, and intermodal transportation. One among the pioneering papers illustrating these applications appeared in 1989, due to Feo and Bard [25], who studied the problem of locating maintenance stations and developing flight schedules that better meet the cyclical demand for maintenance. The problem has been formulated as a large-scale mixed integer program, that is, a minimum cost, multicommodity flow network with integral constraints, where each airplane represents a separate commodity and each arc has an upper and lower capacity of flow. Since obtaining feasible solutions from the relative LP relaxation is difficult, the authors proposed a GRASP. Another interesting paper is due to Argüello *et al.* [26], who described a GRASP to reconstruct aircraft routings in response to groundings and delays experienced over the course of the day. The objective is to minimize the cost of reassigning aircraft to flights taking into account available resources and other system constraints. The proposed GRASP heuristic includes a neighborhood search

technique that takes as input an initial feasible solution, so that the “classical” GRASP construction phase is omitted. Instead, in the procedure, the neighbors of an incumbent solution are generated and evaluated, and the most desirable are placed on an RCL, from which one is randomly selected and becomes the incumbent. Two types of partial route exchange operations are described. The first type is the exchange of flight sequences with identical end points. In the second type, the sequence of flights being exchanged must have the same origination airport, but the termination airports are swapped.

LOGIC, PARTITIONING, AND GRAPH THEORETIC APPLICATIONS

GRASP has been applied to problems in logic, including SAT, MAX-SAT, and logical clause inference. In 1996, Resende and Feo [27] proposed a GRASP for the satisfiability problem that can be applied to both the weighted and unweighted versions of the maximum satisfiability problem. The adaptive greedy function is a hybrid combination of two functions that seek to maximize the number of yet-unsatisfied clauses that become satisfied after the assignment of each construction iteration, and maximize the number of yet-unassigned literals in yet-unsatisfied clauses that become satisfied if opposite assignments were to be made. The local search flips the assignment of each variable, one at a time, checking if the new truth assignment increases the number of satisfied clauses. In 2006, Festa *et al.* [28] proposed a hybrid GRASP with path relinking for the weighted maximum satisfiability problem (MAX-SAT). The authors designed accurate experiments to determine the effect of path relinking on the convergence of the GRASP.

Partitioning problems have been also treated with GRASP. These include number partitioning [29] and software/hardware partitioning [30]. In particular, in Argüello *et al.* [29], randomized methodologies are described for partitioning a finite set of integers into two disjoint subsets such that

the difference of the sums of the elements in the subsets is minimized. Here, the greedy criterion consists in considering only large elements for differencing. In Pu *et al.* [30], the authors propose a hybrid GRASP with tabu search as local search for software/hardware partitioning within timed automata.

Perhaps the largest class of problems for which GRASP has been applied is graph theory. The wide applicability of GRASP to these problems includes among others the maximum independent set problem, the maximum covering problem, the Steiner tree problem, the max cut problem, the feedback vertex set and arc set problems, graph coloring, and the multicriteria minimum spanning tree problem.

For the maximum independent set, in 1994, Feo *et al.* [31] proposed a GRASP whose greedy function orders admissible vertices with respect to the minimum admissible vertex degree, that is, a vertex with the minimum degree and that is not adjacent to any vertex in the current independent set. The neighborhood definition used in the local search is (2,1)-exchange, where two nonadjacent vertices can be added to the current solution if a single vertex from the solution is removed. Resende [32] describes a GRASP for the maximum covering problem. Here, the greedy function is the total weight of the yet-uncovered demand points that become covered after the selection and the local search procedures uses a 2-exchange neighborhood structure.

Martins *et al.* [33] proposed a GRASP for approximately solving general instances of the Steiner problem in graphs. The construction phase is based on the distance network heuristic. A distance network corresponding to the original graph is built and associated with each edge of the distance network is a weight that takes into account the shortest distances in the original graph. With respect to the new weight distribution, Kruskal's algorithm is used to solve the minimum spanning tree problem and the edges in the minimum spanning tree so computed are replaced by the edges in the corresponding shortest paths in the original graph. The local search is based on insertions and eliminations of nodes to and from the current

solution. A parallel version of a GRASP for the Steiner tree problem has been described in Martins *et al.* [34], where the authors propose a local search that uses a combination of key path-based local search and node-based local search.

For the max cut problem, in 2002, Festa *et al.* [35] designed and tested a GRASP, a VNS, a path relinking heuristic, and new hybrid heuristics that combine GRASP, VNS as GRASP local search, and path relinking.

Pardalos *et al.* [36] designed a GRASP for finding approximate solutions to the feedback vertex set problem on a digraph. Several greedy functions were tested, all of them favoring vertices with high degree, while the local search procedure tries at each iteration to eliminate redundant vertices. Festa *et al.* [37] described a set of ANSI standard Fortran 77 subroutines to find approximate solutions of both the feedback vertex set problem and the feedback arc set problem. The GRASP of Pardalos *et al.* is used to produce the approximate solutions of the feedback set problem, while feedback arc set problems are converted into feedback vertex set problems and then solved.

For graph coloring, in 2001, Laguna and Martí [38] proposed a GRASP, whose construction phase greedy function chooses the vertex having the maximum degree among the uncolored vertices adjacent to at least one colored vertex. The local search combines the two smallest cardinality color classes into one and tries to find a valid color for each violating vertex.

Very recently, for the multicriteria minimum spanning tree problem, in 2008, Arroyo *et al.* [39] proposed a GRASP, whose local search tries to improve the current solution by defining a drop-and-add neighborhood, where the spanning trees are represented by Prufer numbers.

LOCATION AND ASSIGNMENT PROBLEMS

GRASP has been successfully used to find approximate solutions to location and assignment problems.

Already in 1992, Klincewicz [40] proposed two heuristics based on tabu search and

GRASP for the p -hub location problem, whose local search procedure is based on the 2-exchange neighborhood. Later, in 2005, Pérez *et al.* [41] described a hybrid GRASP with the path-relinking algorithm for the capacitated p -hub median problem. In this proposal, the greedy evaluation function has two phases: a location phase and an allocation phase. In the location phase, one element is added at each time to the set of hubs, while the allocation phase consists of an allocation to the nearest hub. As local search, the authors proposed a greedy procedure for location and an allocation to the nearest hub. For the p -median and other location problems, efficient multistart hybrid heuristics that combine elements of several traditional metaheuristics including GRASP have been recently proposed by Resende and Werneck [42,43]. Here, the greedy criterion consists in choosing, at each iteration, one among the most profitable facilities, while the local search procedure is based on swapping facilities.

Starting with the pioneering work of Li *et al.* [44], GRASP has been applied to several hard assignment problems, including quadratic, biquadratic, and multidimensional assignment. For the quadratic assignment problem (QAP), Li *et al.* [44] describe a GRASP, whose construction mechanism defines a greedy function on the assignment interaction cost and whose local search procedure is a 2-assignment exchange. The construction phase of the GRASP proposed by Li *et al.* has been later applied by Ahuja *et al.* [45] to generate the initial population of a genetic algorithm for the QAP. In 1998, Mavridou *et al.* [46] proposed a GRASP for finding approximate solutions of the biquadratic assignment problem. As in the case of GRASP for the QAP, the construction phase has two stages. The first stage simultaneously makes four assignments, selecting the pairs corresponding to the smallest interaction costs, while the second stage makes the remaining assignments, one at time. The greedy function in the second stage selects the assignment corresponding to the minimum interaction cost with respect to the already-made assignments. In the local search phase, 2-exchange is applied to the

permutation constructed in the first phase. An interesting study has been conducted, in 1999, by Fleurent and Glover [47]. In their paper, they showed that the GRASP for QAP of Li *et al.* [44] can be improved upon by using memory strategies, such as learning, intensification, candidate list strategies, and the Proximate Optimally Principle (POP). For the multidimensional assignment problem, Robertson [48], in 2001, proposed four GRASP implementations by combining two construction methods (randomized greedy and randomized max regret) and two local search methods (2-exchange and variable depth exchange). The greedy function of the randomized max regret construction method is a measure of the competition between the two leading cost candidates, while the maximum regret value corresponds to the candidate assignment that has the largest winning margin between itself and its next highest competitor. The variable depth exchange is an extension of the 2-exchange method that allows a more extensive search of the surrounding neighborhood space.

MANUFACTURING

GRASP has been applied to solve several optimization problems arising in manufacturing. The first paper that is an example of this kind of application is due to Feo and Bard [49], who, in 1989, proposed a method for minimizing the sum of tool setup and volume removal times associated with metal cutting operations on a flexible machine. The problem was modeled as an integer program and relaxed into a min-cut problem on a simple network. After obtaining a tentative solution, the authors used a GRASP to identify good feasible points corresponding to alternative process plans. The same authors [50], in 1991, designed an algorithm for the manufacturing equipment selection problem, where the objective is to determine how many of each machine type to purchase and for what fraction of the time each piece of equipment will be configured for a particular type of operation. The problem has been transformed into a mixed integer linear program (MILP) and a depth-first branch and bound algorithm has been used, employing the greedy

randomized set covering heuristic of Feo and Resende [7].

More recently, for constrained two-dimensional nonguillotine cutting problems, Alvarez-Valdes *et al.* [51], in 2005, proposed a GRASP, whose construction mechanism takes the smallest rectangle breaking the ties by the nearest distance to a corner of the stock rectangle. Then, two criteria have been considered to select the piece: (i) the first piece in an ordered list, giving priority to pieces that must be cut; (ii) the piece producing the largest increase in the objective function. In 2008, Monkman *et al.* [52] described a production scheduling heuristic for an electronics manufacturer with sequence-dependent setup costs. The problem studied here involves assignment, sequencing, and time-scheduling steps, and has been modeled as a traveling salesman subset-tour problem. For the sequencing step, the authors proposed a GRASP, whose construction phase uses a cardinality-based RCL and the greedy function takes into account the cost associated with the arcs of the underlying graph. The local search uses two different neighborhoods: a node elimination and a node swap neighborhood.

TELECOMMUNICATIONS

Telecommunications and network design are two fields of quite a large number of applications of GRASP. In the following, only some recent papers will be cited.

Liu *et al.* [53], in 2000, proposed a hybrid GRASP for frequency assignment in mobile radio networks, whose local search is a simulated annealing and whose construction phase uses two greedy functions. The first chooses a vertex from the set of unselected vertices with high saturation degrees, while the second function is used to assign a frequency to the selected vertex. Prais and Ribeiro [54] designed a GRASP for a matrix decomposition problem arising in the context of traffic assignment in communication satellites. The local search phase of the GRASP proposed is based on a new neighborhood, defined by constructive and destructive moves. In 2003, Amaldi *et al.* [55] proposed

a GRASP and a tabu search to efficiently solve the downlink base station (BS) location problem. Here, during the local search, the following moves are considered: removing a BS, installing a new BS, removing an existing BS, and installing a new one (swap). The output GRASP solution is used as initial solution for a tabu search algorithm. In 2008, Commander *et al.* [56] designed and implemented a GRASP for the cooperative communication problem on *ad hoc* networks, where the problem consists in maximizing the amount of connectivity among a set of users, subject to constraints on the maximum distance traveled, as well as restrictions on what types of movement can be performed. The greedy function value of each candidate element is a measure of additional connections created by its insertion in the partial solution under construction. The local search procedure is based on a perturbation function consisting of selecting a wireless agent and rerouting.

APPLICATIONS IN BIOLOGY

It is only in the past few years that it has been shown that a large number of molecular biology problems can be formulated as combinatorial optimization problems, usually computationally intractable so as to employ heuristic methods to find good solutions in a reasonable amount of running time. Brown *et al.* [57] proposed a GRASP for selecting a population subset for use in a high-density genetic mapping project. At each iteration of the construction phase, the authors add to the partial solution, one among the r unchosen population members that most improve the objective function value. The authors investigated very small-sized RCL (i.e., $r = 3$ and $r = 5$) and the local search they implemented removes from the current solution some members and greedily includes other members, until no further improving exchange can be done.

For the phylogeny problem (consisting in finding a phylogeny with the minimum number of evolutionary steps—the so-called parsimony criterion), Andreatta and Ribeiro [58] and later Ribeiro and Vianna [59] proposed

a GRASP, and a VNS and a GRASP, which uses variable neighborhood descent for local search, respectively.

Phylogenetic footprints are short pieces of no-coding DNA sequences in genes that are conserved between evolutionarily distant species. Fried *et al.* [60] showed that solving the footprint sorting problem requires the solution of a minimum weight vertex feedback set problem and for solving the latter, they used the GRASP provided in Festa *et al.* [37].

In 2007, Festa [61] proposed a GRASP to find improved solutions for the far from most string problem, where the objective is to determine a sequence far from most of the sequences in a given input set. In this case, it is intuitive to relate the greedy function to the occurrence of each character in a given position, while to perform the local search phase the 2-exchange algorithm has been used. A solution for the far from most string problem can help, for example, to identify a sequence fragment that distinguishes the pathogens from the host, so that the potential exists to create a drug that harms several but not all pathogens.

EFFECTIVE APPLICATION OF GUIDED LOCAL SEARCH

CHRISTOS VOUDOURIS
EDWARD P. K. TSANG
ABDULLAH ALSHEDDY
School of Computer Science and
Electronic Engineering,
University of Essex, Colchester,
UK

Guided local search (GLS) is a penalty-based approach that sits on top of local search (LS) methods to bring them out of local minima. GLS heavily employs information about the search history and the structure of solutions to distribute the search effort in the various regions of the search space. The procedure of GLS is prescriptive and relatively simple to implement. As it is the case with other metaheuristics, it requires an LS method to be readily available for the problem at hand. This is both, in terms of a way of producing an initial solution either randomly or heuristically and also in terms of a local improvement procedure which can iteratively optimize a given solution.

To assist with implementation of the technique, we provide the detailed pseudocode for

the main GLS algorithm. We also detail the two related methods of FLS and guided fast local search (GFLS) which can improve the running times of LS (in the case of FLS) and integrate tighter LS with GLS (in the case of GFLS). The set of techniques presented constitute the foundations of the GLS approach and they can be applied with little modifications to a diverse range of problems from routing and scheduling to assignment problems and constraint optimization, including large-scale instances and real-world applications. Suggestions and insights on the practical implementation of the methods in software are provided and discussed.

One important element in the effective application of GLS to a specific problem is the definition of features and their costs so that GLS can effectively guide LS and efficiently distribute the search effort. We pay special attention to this subject, providing examples of possible features to use to apply GLS to common classes of problems.

IMPLEMENTING GUIDED LOCAL SEARCH

We start our detailed presentation of the techniques with the main GLS algorithm. The pseudocode for the algorithm is provided below:

```
procedure GuidedLocalSearch( $p, g, \lambda, [I_1, \dots, I_M], [c_1, \dots, c_M], M$ )  
begin  
   $k \leftarrow 0$ ;  
   $s_0 \leftarrow \text{ConstructionMethod}(p)$ ;  
  /* set all penalties to 0 */  
  for  $i \leftarrow 1$  until  $M$  do  
     $p_i \leftarrow 0$ ;  
  /* define the augmented objective function */  
   $h \leftarrow g + \lambda * \sum p_i * I_i$ ;  
  while NOT StoppingCriterion do  
    begin  
       $s_{k+1} \leftarrow \text{ImprovementMethod}(s_k, h)$ ;  
      /* compute the utility of features */  
      for  $i \leftarrow 1$  until  $M$  do  
         $\text{util}_i \leftarrow I_i(s_{k+1}) * c_i / (1 + p_i)$ ;  
      /* penalize features with maximum utility */
```

```

for each  $i$  such that  $util_i$  is maximum do
     $p_i \leftarrow p_i + 1$ ;
     $k \leftarrow k+1$ ;
end
 $s^* \leftarrow$  best solution found with respect to objective function  $g$ ;
return  $s^*$ ;
end

```

where p is the problem, g the objective function, h the augmented objective function, λ the lambda parameter, I_i the indicator function of feature i , c_i the cost of feature i , M the number of features, p_i the penalty of feature i , *ConstructionMethod*(p) the method for constructing a initial solution for problem p , and *ImprovementMethod*(s_k, h) the method for improving solution s_k according to the augmented objective function h .

Two external methods, usually part of a typical LS procedure, are invoked from within the GLS algorithm, namely the *ConstructionMethod* and the *ImprovementMethod*. GLS starts the searching process from an initial solution. This is generated by the *ConstructionMethod*. The solution can be generated either randomly or heuristically, based on some known techniques for constructing solutions for the particular problem. We found that GLS is not very sensitive to the starting solution; provided sufficient time is available to the algorithm to explore the search space of the problem. A method for improving the solution is also required. The *ImprovementMethod* can be a simple LS algorithm or a more sophisticated one such as Variable Neighborhood Search [1], Variable Depth Search [2], Ejection Chains [3] or combinations of LS methods with exact search algorithms [4]. The reader should note here that the *ImprovementMethod* uses the augmented objective function (h) rather than the original one (g) as also shown in the pseudocode above.

It is not essential for the improvement method to generate high quality local minima. Experiments with GLS and various TSP heuristics reported in Ref. 5 have shown that high quality local minima take time to produce, resulting in less intervention by GLS in the overall allocated search time. This may sometimes lead to inferior results compared

to a simpler but more computationally efficient improvement method.

Apart from the construction method and the improvement method mentioned above, which are specific to the problem at hand, the rest of the algorithm presented above is generic and rather straightforward. We provide below suggestions and insights on how to efficiently implement the various key components of the algorithm.

Utility Function

The penalties of features are initialized to zero. At each iteration, the improvement method is called which will return a local minimum. Note here that the solution returned may in fact not be a “true” local minimum (e.g., because of penalties introduced by GLS or limited neighbors considered by the improvement method) but for the sake of simplicity, we will refer to it as one. At this local minimum, GLS will have to select which features to penalize to help the LS to escape. The utility function is defined for that purpose. The utility of each feature exhibited in the returned local minimum is calculated, and those features with maximum utility are penalized by incrementing their penalty values.

The indicator functions I_i that define the features rarely need to be implemented in software code. Looking at the values of the decision variables, one can directly identify the features present in a local minimum. When this is not possible, data structures with constant time deletion/addition operations (e.g. based on double-linked lists) can incrementally maintain the set of features present in the working solution, avoiding the need for an expensive computation to detect features from scratch every time GLS reaches a local minimum.

The selection of features to penalize can also be efficiently implemented by using the same loop for computing the utility formula for features present in the local minimum (the rest can be ignored) and also placing features with maximum utility in a vector. With a second loop, the features with maximum utility contained in this vector have their penalties incremented by one.

λ Parameter

The parameter λ is the only parameter to the GLS method (at least in its basic version) and in general, it is instance dependent and more specifically linked to the values that objective function takes as the search moves within the landscape of the problem. It has been observed that, for several problems, a good value for λ can be calculated by dividing the value of the objective function in a local minimum with the average number of features present. In these problems, λ is dynamically computed after the first local minimum and before penalizing features for the first time. Providing an α parameter, which is relatively instance-independent, λ is calculated by the following formula:

$$\lambda = \alpha \times g(s^*)/Fs^*, \quad (1)$$

where g is the objective function of the problem, s^* is a local minimum, and Fs^* is the number of features present in s^* .

Tuning α can result in λ values, which work for many instances of a problem class. Once tuned, α can be fixed in industrialized

versions of software, resulting in a ready-to-use GLS algorithm for the end user.

Note here that depending on the value of λ (or α), several penalty cycles may be required before a move is executed out of a local minimum. This should not be viewed as an undesirable situation and it should not motivate using high λ (or α) values to quickly escape from local minima. The very uncertainty in the information used in guiding the search (e.g., feature costs) makes necessary the testing of the GLS decisions against the landscape of the problem in a gradual manner. Smaller penalty values tend to help GLS find the “best” escape route out of local minima without unnecessarily distorting the landscape. This approach is illustrated in Fig. 1.

Augmented Objective Function

It is important to mention that although the search in GLS uses the augmented objective function, the program should keep track of the actual objective value in all operations relating to storing the best solution or finding a new best solution. This is not limited to the solutions accepted by LS but also includes those evaluated. The reason is that LS uses the augmented objective function and, hence, a move that generates a new best solution may be missed. To the contrary, keeping track of the value of the augmented objective value (e.g., after adding the penalties) is not necessary since LS methods will be looking only at the differences in the augmented objective value when evaluating LS moves.

Figure 1. GLS is escaping from a valley (i.e., local minimum) in the landscape by increasing the objective function value for its solutions. This is conducted in a gradual and focused manner so that search is guided toward local minima of higher quality.

However, the move evaluation mechanism needs to be revised to work efficiently with the augmented objective function.

Normally, the move evaluation mechanism does not directly evaluate the objective value of the new solution generated by the move. Instead, it calculates the difference Δg in the objective function. This difference should be combined with the difference in the amount of penalties. This can be easily done and has no significant impact on the time needed to evaluate a move. In particular, we have to take into account only features that change state (being deleted or added). The penalties of the features deleted are summed together. The same is done for the penalties of features added. The change in the amount of penalties due to the move is then simply given by the difference

$$\sum_{\text{over all features } j \text{ added}} p_j - \sum_{\text{over all features } k \text{ deleted}} p_k, \quad (2)$$

which then has to be multiplied by λ and added to Δg .

Stopping Criterion

There are many choices possible for the *StoppingCriterion* of the algorithm. Since GLS is not trapped in local minima, there is no obvious point when to stop the algorithm. Like in other metaheuristics, a measure related to the length of the search process is usually used. A limit on the number of moves performed, the number of moves evaluated, or the CPU time spent by the algorithm are examples of such a

measure. A lower bound can be utilized as a stopping criterion, if it is known, by setting the excess above the lower bound that we require to be achieved. Criteria can also be combined to allow for a more flexible way to stop the GLS method. The idea of threshold value was proposed as a termination condition for every GLS stage in Ref. 6.

IMPLEMENTING FAST LOCAL SEARCH

FLS is designed to reduce the running times of LS algorithms. The idea of FLS is to speed up neighborhood search by exploiting historical information that would help to ignore parts of the neighborhood which are unlikely to yield better solutions. The approach is similar to candidate list strategies as used in Tabu Search [3] and other metaheuristics.

In FLS, the problem's neighborhood is broken down into a number of subneighborhoods and an activation bit is attached to each one of them (bit_i). The idea is to examine subneighborhoods in a given order, searching only those with the activation bit set to one. The neighborhood search process does not restart whenever we find a better solution but it continues with the next subneighborhood in the given order. The initial values of the bits are given as an input to the procedure, which allows the procedure to be focused on certain subneighborhoods and not the whole neighborhood, which may be a large one. The detailed pseudocode for FLS is provided below.

procedure FastLocalSearch($s, h, [bit_1, \dots, bit_L], L$)
begin

```

  while  $\exists j, bit_j = 1$  do
    /* i.e. while active sub-neighborhood exists */
    for  $i \leftarrow 1$  until  $L$  do
      begin
        if  $bit_i = 1$  then
          /* search sub-neighborhood  $i$  */
          begin
            Moves  $\leftarrow$  MovesForSubneighborhood( $i$ );
            for each move  $m$  in Moves do
              begin
                 $s' \leftarrow m(s)$ ;

```

```

/* s' is the result of move m */
if h(s') < h(s) then
/* minimization case is assumed here */
begin
  /* spread activation */
  ActivateSet ← SubneighborhoodsForMove(m);
  for each sub-neighborhood j
  in ActivateSet do
    bitj ← 1;
    s ← s';
  goto ImprovingMoveFound
end
end
biti ← 0; /* no improving move found */
end
ImprovingMoveFound:
  continue;
end;
return s;
end

```

where s is the solution, h the augmented objective function, L the number of subneighborhoods, bit_i the activation bit for subneighborhood i , *MovesForSubneighborhood*(i) the method which returns the set of moves contained in subneighborhood i , and *SubneighborhoodsForMove*(m) the method which returns the set of subneighborhoods to activate when move m is performed.

Two components in FLS procedure need to be defined. They are the breaking-down of the neighborhood into subneighborhoods and the mapping from moves to subneighborhoods for spreading activation, both of which are dependent on the move operator used. In general, the move operator depends on the solution representation. Fortunately, several problems share the same solution representation which is typically based on some well-known simple or composite combinatorial structure (e.g., selection, permutation, partition, composition, path, cyclic path, tree, graph, etc.). This allows us to use the same move operators for many different problems (e.g., 1-Opt, 2-Opt, Swaps, Insertions, etc.). Mapping subneighborhoods to moves (*MovesForSubneighborhood* procedure) can be defined by looking at the implementation of a typical LS procedure for the problem. This implementation, at its core, will usually contain a number of nested for-loops for

generating all possible move combinations. The variable in the outer-most loop in the move generation code can be used to define the subneighborhoods. The moves in each subneighborhood will be those generated by the inner loops for the particular subneighborhood index value at the outer-most loop.

Subneighborhoods can be overlapping. FLS usually examines limited numbers of moves compared to exhaustive neighborhood search methods and therefore duplication of moves is not a problem. Moreover, this can be desirable sometimes to give a greater range to each subneighborhood. Since not all subneighborhoods are active in the same iteration, if there is no overlapping, some of improving moves may be missed. The spreading activation method (*SubneighborhoodsForMove* procedure) returns a set of subneighborhoods to activate after a move is performed. The lower bound for this set is the subneighborhood where the move originated. The upper bound (although not useful) is all the subneighborhoods in the problem.

This last method can be defined by looking at the particular move operator used. Moves will affect part of the solution directly or indirectly while leaving other parts unaffected. If a subneighborhood contains affected parts, then it needs to be activated since an opportunity could arise there for an improving move as a result of the original

move performed. The FLS loop is settling down in a local minimum when all the bits of subneighborhoods turn to zero (i.e., no improving move can be found in any of the subneighborhoods).

FLS in that respect is similar to other LS procedures. The main differences are that the method can be focused to search particular parts of the overall neighborhood and secondly, it works in an opportunistic way, looking at parts of the solution which are likely to contain improving moves rather than the whole solution. In the next section, we look at GFLS, which uses FLS as its improvement method.

IMPLEMENTING GUIDED FAST LOCAL SEARCH

The GFLS is similar to GLS explained previously. All differences relate to the manipulation of activation bits for the purpose of focusing FLS. Initially, all bits are initialized to one. This enables all subneighborhoods to be examined by the first call to FLS. At each subsequent call to FLS, only the subneighborhoods that relate to the features penalized by GLS will be examined. The detailed pseudocode realizing this scheme is provided below:

```
procedure GuidedFastLocalSearch( $p, g, \lambda, [I_1, \dots, I_M], [c_1, \dots, c_M], M, L$ )
begin
   $k \leftarrow 0$ ;
   $s_0 \leftarrow \text{ConstructionMethod}(p)$ ;
  /* set all penalties to 0 */
  for  $i \leftarrow 1$  until  $M$  do
     $p_i \leftarrow 0$ ;
  /* set all sub-neighborhoods to the active state */
  for  $i \leftarrow 1$  until  $L$  do
     $\text{bit}_i \leftarrow 1$ ;
  /* define the augmented objective function */
   $h \leftarrow g + \lambda * \sum p_i * I_i$ ;
  while NOT StoppingCriterion do
    begin
       $s_{k+1} \leftarrow \text{FastLocalSearch}(s_k, h, [\text{bit}_1, \dots, \text{bit}_L], L)$ ;
      /* compute the utility of features */
      for  $i \leftarrow 1$  until  $M$  do
         $\text{util}_i \leftarrow I_i(s_{k+1}) * c_i / (1 + p_i)$ ;
      /* penalize features with maximum utility */
      for each  $i$  such that  $\text{util}_i$  is maximum do
        begin
           $p_i \leftarrow p_i + 1$ ;
          /* activate sub-neighborhoods related
          to penalized feature  $i$  */
          ActivateSet  $\leftarrow \text{SubneighborhoodsForFeature}(i)$ ;
          for each sub-neighborhood  $j$  in ActivateSet do
             $\text{bit}_j \leftarrow 1$ ;
        end
      end
       $k \leftarrow k + 1$ ;
    end
   $s^* \leftarrow$  best solution found with respect to objective function  $g$ ;
  return  $s^*$ ;
end
```

where p is the problem, g the objective function, h the augmented objective function, λ the lambda parameter, I_i the indicator function of feature i , c_i the cost of feature i , M the number of features, p_i the penalty of feature i , L the number of subneighborhoods, bit_i the activation bit for subneighborhood i , $ConstructionMethod(p)$ the method for constructing an initial solution for problem p , $FastLocalSearch(s_k, h, [bit_1, \dots, bit_L], L)$ the FLS method as depicted in the previous section, and $SubneighborhoodsForFeature(i)$ the method which returns the set of subneighborhoods to activate when feature i is penalized.

GFLS introduces the new method *SubneighborhoodsForFeature*, similar in function to the *SubneighborhoodsForMove* method, in the stand-alone FLS procedure. Its task is to identify the subneighborhoods that are related to a penalized feature. The *SubneighborhoodsForFeature* method is usually defined based on an analysis of the move operator. When penalties are increased, the search should focus on moves which remove or have the potential to remove penalized features from the solution. The subneighborhoods, which contain such moves, are prime candidates for activation when FLS restarts after each penalty application cycle.

DEFINING FEATURES AND THEIR COSTS

Features are not necessarily specific to a particular problem and they can be used in several problems of similar structure. Therefore, for each category of applications, we provide examples of features that can be deployed in the context of various problems. The reader may find them helpful and use them in his/her own optimization application. Furthermore, real-world problems, which sometimes incorporate elements from several academic problems, can benefit from using more than one feature-set to guide LS to optimize better all different terms of a complex objective function with several components.

Features for Routing and Scheduling Problems

In routing and scheduling problems, travel (or setup) times are usually a key factor of

cost. This could be expressed in terms of minimizing the travel time required by a vehicle to travel between customers or the setup time for a machine to be utilized from one activity to the next. Problems in this category include the traveling salesman problem (TSP), vehicle routing problem (VRP), and machine scheduling with sequence-dependent setup times.

Travel or setup times are modeled as edges in a path or graph structure commonly used to represent the solution of these problems. An objective function is defined (at least partly) as the sum of lengths for the edges used by the solution. In such cases, edges are ideal GLS features. A solution either contains an edge or not. Furthermore, each edge has a cost equal to its length. We can define a feature for each possible edge and assign a cost to it that equals the edge length. GLS quickly identifies and penalizes long and costly edges guiding LS to high quality solutions which use as much as possible the available short edges.

As an alternative, a slightly different feature cost strategy was proposed in Refs 7 and 8 for the VRP. The authors there consider the relative arc length between two customers according to the rest of customer population (i.e., $d_{ij} / \text{avg}(d_{ij})$) rather than d_{ij} as the feature cost. The idea is that this variation would lead to a more balanced arc selection for penalization as compared to the frequently employed strategy (only d_{ij}).

Features for Assignment and Allocation Problems

In assignment problems, a set of items has to be assigned to another set of items (e.g., airplanes to flights, locations to facilities, people to work etc.). Each assignment of item i to item j usually carries a cost. Assignment problems normally include constraints that must be satisfied (e.g., capacity or compatibility constraints). The assignment of item i to item j can be seen as a solution property which is either present in the solution or not. Since each assignment also carries a cost, this is another good and straightforward example of a feature to be used in a GLS implementation.

Assignment problems can be used to model resource allocation applications. A special but important case in resource allocation is when the resources available are not sufficient to service all requests. Usually, the objective function will contain a sum of costs for the unallocated requests, which is to be minimized. The cost incurred when a request is unallocated will reflect the importance of the request or the revenue lost in the particular scenario.

A possible feature to consider for these problems is whether a request is unallocated. If the request is unallocated, then a cost is incurred in the objective function, which we can use as the feature cost to guide LS. The number of features in a problem is equal to the number of requests that may be left unallocated, one for each request. There may be hard constraints which state that certain requests should always be allocated a resource. There is no need to define a feature for such hard constraints.

In some variations of the problem such as the quadratic assignment problem (QAP), the cost function is more complicated and assignments have an indirect impact on the cost. Even in these cases, we found that the GLS can generate good results by assigning to all features the same feature costs (e.g., equal to one or some other arbitrary value). Although, GLS is not guiding the improvement method to good solutions (since this information is difficult to extract from the objective function), it can still diversify the search because of the penalty memory incorporated and it is capable of producing results comparable to popular heuristic methods.

Features for Constraint Optimization Problems

Several combinatorial optimization problems concern the search for a feasible solution with respect to a set of constraints. In some cases, finding such a solution is impossible, and then the task gets modified into finding a solution that minimizes the number of unsatisfied constraints (relaxations).

Constraint violations may have costs (weights) associated with them, in which case the sum of constraint violation costs is to be minimized. LS usually considers the number of constraint violations (or their weighted

sum) as the objective function even in cases where the goal is to find a solution, which satisfies all the constraints. Constraints by their nature can be easily used as features. They can be modeled by indicator functions and they also incur a cost (i.e., when violated/relaxed), which can be used as their feature cost. Problems which can benefit from this modeling include the constraint satisfaction and partial constraint satisfaction problem, the famous SAT and its MAX-SAT variant, graph coloring, various frequency assignment problems [9], and others.

Features for Continuous Optimization Problems

The potential applications of GLS are not limited to optimization problems of a discrete nature, as shown in previous categories of applications, but can also be applied to difficult continuous optimization problems. In the optimization of real-valued functions, no features can be deduced from the structure of the objective function. In this case, artificial solution features can be created. A simple setting, for instance, is to divide the domains of variables into a number of nonoverlapping and equal-sized intervals. Penalizing a subdomain discourages the LS method from revisiting this area in the search space in future iterations.

Table 1 provides a summary of the applications and features for each category as discussed in this section. In the next section, we provide an example by looking at how GLS can be applied to the TSP.

EXAMPLE: THE TRAVELING SALESMAN PROBLEM

There are many variations of the TSP. In here, we examine the classic symmetric TSP. The problem is defined by N cities and a symmetric distance matrix $D = [d_{ij}]$ which gives the distance between any two cities i and j . The goal in TSP is to find a tour (i.e., closed path), which visits each city exactly once and is of minimum length. A tour can be represented as a cyclic permutation π on the N cities if we interpret $\pi(i)$ to be the city

Table 1. Common Features Used for Each Application Category

Category	Common Features
Routing	Edges in a graph, which model the travel between cities, customers, and so on. The travel time is used as feature cost for each edge
Scheduling	Edges in a graph, which model the sequence of the scheduled processes. The setup time is used as feature cost for each edge
Assignment	Every possible match (i.e. assignment) between items can be a feature, which has its (unique) cost
Allocation	The allocation of each request is a feature. Feature cost can be set to the cost of not allocating a particular request
Constrained optimization	Constraint violation is a common feature; unless constraints vary in their importance, all corresponding features are set to equal cost (e.g., 1)
Continuous optimization	Whether a variable is assigned a value within a certain interval; features are set to equal cost

visited after city $i, i = 1, \dots, N$. The cost of a permutation is defined as

$$g(\pi) = \sum_{i=1}^N d_{i\pi(i)} \quad (3)$$

and gives the cost function of the TSP.

Construction Method

A simple construction method is to generate a random tour. More advanced TSP heuristics can be used if we require a higher quality starting solution to be generated [10]. This is useful in real-time/on-line applications where a good tour may be needed very early in the search process in case the user interrupts the algorithm. If there are no concerns like that, then a random tour generator suffices since the GLS metaheuristic tends to be relatively insensitive to the starting solution and capable of finding high quality solutions even if left to run for a relatively short time.

Improvement Method

Most improvement methods for the TSP are based on the k -Opt moves. Using k -Opt moves, neighboring solutions can be obtained by deleting k edges from the current tour and reconnecting the resulting paths using k new edges. The reader can consider using the simple 2-Opt [11] method, which in addition to its simplicity, is very effective when combined with GLS. With 2-Opt, a neighboring solution is obtained from the current solution

by deleting two edges, reversing one of the resulting paths, and reconnecting the tour. Computing incrementally the change in solution cost by a 2-Opt move is relatively simple. Let us assume that edges $e1, e2$ are removed and edges $e3, e4$ are added with lengths $d1, d2, d3$, and $d4$ respectively. The change in cost is the following:

$$d3 + d4 - d1 - d2. \quad (4)$$

When we discuss the features used in the TSP, we will explain how this evaluation mechanism is revised to account for penalty changes in the augmented objective function.

Guided Local Search

For the TSP, a tour includes a number of edges and the solution cost (tour length) is given by the sum of the lengths of the edges in the tour (3). As mentioned in the section titled “Features for Routing and Scheduling Problems,” edges are ideal features for routing problems such as the TSP. First, a tour either includes an edge or not and second, each edge incurs a cost in the objective function equal to the edge length, as this is given by the distance matrix $D = [d_{ij}]$ of the problem. A set of features can be defined by considering all possible undirected edges $e_{ij}(i = 1 \dots N, j = i+1 \dots N, i \neq j)$ that may appear in a tour with feature costs given by the edge lengths d_{ij} . To each edge e_{ij} connecting cities i and city j is attached a penalty p_{ij}

initially set to zero, which is increased by GLS during search. When implementing the GLS algorithm for the TSP, the edge penalties can be arranged in a symmetric penalty matrix $P = [p_{ij}]$. Penalties have to be combined with the problem's objective function to form the augmented objective function which is minimized by LS. We therefore need to consider the auxiliary distance matrix

$$D' = D + \lambda \cdot P = [d_{ij} + \lambda \cdot p_{ij}], \quad (5)$$

LS must use D' instead of D in move evaluations. GLS modifies P and (through that) D' whenever LS reaches a local minimum.

In order to implement this, we revise the incremental move evaluation formula (Eq. 7) to take into account the edge penalties and also the λ parameter. If $p1, p2, p3$, and $p4$ are the penalties associated with edges $e1, e2, e3$, and $e4$ respectively, the revised version of Equation (7) is as follows:

$$(d3 + d4 - d1 - d2) + \lambda(p3 + p4 - p1 - p2). \quad (6)$$

Similarly, we can implement GLS for higher order k-Opt moves.

The edges penalized in a local minimum are selected according to the utility function which for the TSP takes the following form:

$$Util(tour, e_{ij}) = I_{e_{ij}}(tour) \cdot \frac{d_{ij}}{1 + p_{ij}}, \quad (7)$$

where

$$I_{e_{ij}}(tour) = \begin{cases} 1, & e_{ij} \in tour \\ 0, & e_{ij} \notin tour \end{cases} \quad (8)$$

The only parameter of GLS that requires tuning is the λ parameter. Alternatively, we can tune the a (α) parameter which is defined in “ λ Parameter” and it is relatively instance-independent. For 2-Opt, the following range for a generates high quality solutions for instances in the TSPLib [12].

$$1/8 \leq a \leq 1/2. \quad (9)$$

The reader may refer to Ref. 5 for more details on the experimentation procedure and the full set of results.

Guided Fast Local Search

We can exploit the way LS works on the TSP to partition the neighborhood into subneighborhoods as required by GFLS. Each city in the problem may be seen as defining a subneighborhood, which contains all 2-Opt edge exchanges, removing either one of the edges adjacent to the city. For a problem with N cities, the neighborhood is partitioned into N subneighborhoods, one for each city in the instance.

The subneighborhoods to be activated after a move is executed are those cities that are at the ends of the edges removed or added by the move. Finally, the subneighborhoods activated after penalization are those defined by the cities at the ends of the edge(s) penalized. There is a good chance that these subneighborhoods will include moves that remove one or more of the penalized edges.

SUMMARY AND CONCLUSIONS

It is relatively easy to adapt GLS to the different problems. Although LS is problem dependent, the other structures of GLS and also GFLS are problem independent. Moreover, a rather mechanical, step-by-step procedure can usually be followed when GLS or GFLS is applied to a new problem (i.e., implement an LS procedure, identify features, assign costs, define subneighborhoods, etc.). This approach makes GLS and GFLS easier to use by nonspecialists and software engineers.

This can be aided further by the development of libraries and toolkits which can provide to end users ready-to-use implementations of common metaheuristic methods. As an example of that, GLS and FLS have been incorporated into iOpt, a software toolkit for heuristic search methods [13], and iSchedule [14], which is an extension to iOpt for planning and scheduling applications (e.g., for solving problems such as the VRP [15]).

Examples of computer programs and demos of algorithms can help researchers and practitioners understand and effectively apply the various metaheuristic techniques. On that front, Essex University's website [16] provides experimental software for the

application of GLS and FLS on a variety of other problems, including the maximum channel assignment problem, TSP, and QAP.

EFFECTIVE APPLICATION OF SIMULATED ANNEALING

JEFFREY W. OHLMANN

Department of Management Sciences,
University of Iowa, Iowa City, Iowa

JON W. VAN LAARHOVEN

Department of Applied Mathematics and
Computational Sciences, University of
Iowa, Iowa City, Iowa

Simulated annealing (SA) is a stochastic local search algorithm in which a probabilistic transition mechanism governs the acceptance or rejection of each move from a current solution x to a candidate solution y . The salient feature of SA is its ability to escape from becoming trapped in local minima by accepting nonimproving solutions. At each iteration, SA accepts the candidate solution with a probability dependent on two factors: (i) the relative cost of the candidate solution versus the current solution and (ii) the value of a control parameter referred to the *temperature*. The temperature parameter derives its name from the algorithm's thermodynamic analogy to the metallurgical process of annealing; as in the physical process of heating material and cooling it to change its properties, the manipulation of the temperature parameter is often critical to the success of SA on an optimization problem. See ***Axiomatic Measures of Risk and Risk-Value Models*** for additional background information on the simulated annealing algorithm.

ALGORITHMIC IMPLEMENTATION

To implement an SA algorithm, the user must define a precise problem representation, a method for generating candidate solutions, and a cooling schedule to control the transition mechanism over the course of the algorithm. In this section, we elaborate on implications of the design of these features.

To aid our exposition, we will rely on Algorithm 1, which illustrates the pseudocode for a general SA algorithm for a minimization problem. Adhering to traditional implementations, Algorithm 1 incorporates a probabilistic mechanism for transitioning between solutions based on the Boltzmann distribution, although the acceptance function in Line 13 can certainly be modified, for example, see the section titled “Orthogonal Stock-Cutting Problem.”

Problem-Specific Design Choices

The first step in applying any solution technique to an optimization problem is clearly delineating the problem, keeping in mind that there may exist multiple ways to represent the problem, and that the choice of representation has implications on solving the problem. By characterizing what constitutes a feasible solution and whether infeasible solutions will be considered along the search path, the problem representation will define the solution space S . Furthermore, to evaluate a solution, the user must specify a cost function $c : S \rightarrow \mathbb{R}$.

SA considers moves from a current solution by generating candidate solutions from a defined neighborhood (Line 5). To facilitate the local search procedure, a neighborhood function $N : S \rightarrow 2^S$ generates candidate solutions for consideration. For $x \in S$, $N(x) \subseteq S$ is called the *neighborhood* of x , typically consisting of solutions that share some structural commonality with x . It is most common to define $N(x)$ as the set of all possible solutions that can be obtained by applying a perturbation operator to x . For example, if $x = [1, 2, 3]$, then with respect to an exchange operation on every pair of elements, $N(x) = \{[2, 1, 3]; [1, 3, 2]; [3, 2, 1]\}$.

To make a local search algorithm such as SA more efficient, it is important to take advantage of the relationship between a current solution x and a neighbor solution

$y \in N(x)$ so that $c(y)$ can be updated from $c(x)$ rather than completely recalculated. The use of appropriate data structures can further facilitate fast manipulations. When evaluation of the cost difference between two solutions is computationally expensive, Tovey [1] advocates the use of a surrogate function to approximate the cost of a neighbor solution at most iterations and occasionally calculating the true solution cost, for example, when neighbor solution is accepted.

SA typically generates a neighbor solution by randomly sampling the neighborhood. An

alternative is to cyclically sample the neighborhood so that a transition to a neighbor solution would not be considered twice until all other neighbor solutions are considered once. However, due to the stochastic nature of SA, the implications of cyclic sampling are difficult to anticipate and it may improve or deteriorate performance. As opposed to randomly generating a neighbor solution, Fox [2] proposes the development of mechanisms that “intelligently” generate neighbors similar to the intensification and diversification protocol of tabu search.

Algorithm 1. Simulated annealing for minimization problems.

```

1  Initialize solution,  $x$ , and best solution found,  $x_{\text{best}} \leftarrow x$ ;
2  Initialize temperature,  $\tau$ ;
3  while Outer termination criteria not satisfied do
4      while Inner termination criteria not satisfied do
5          Generate neighbor solution  $y \in N(x)$ ;
6          if  $c(y) \leq c(x)$  then
7               $x \leftarrow y$ ;
8              if  $c(x) < c(x_{\text{best}})$  then
9                   $x_{\text{best}} \leftarrow x$ ;
10             end
11         else
12             Generate uniform (0,1) random variable  $u$ ;
13             if  $\exp\left(\frac{c(x)-c(y)}{\tau}\right) > u$  then
14                  $x \leftarrow y$ ;
15             end
16         end
17     end
18     Update  $\tau$  via cooling function;
19 end
20 Return  $x_{\text{best}}$ ;

```

The choice of neighborhood can have a significant impact on the effectiveness of a SA algorithm. Determining a neighborhood that facilitates an effective search within SA is largely dependent on the problem domain and may require extensive experimentation as well as problem insight. Ideally, the selected neighborhood should impose a topology that avoids numerous deep local minima that can hinder SA's ability to escape their basins of attraction. Furthermore, neighborhoods that facilitate *reachability*, that is, every solution can be reached from any other through a series of transitions, are theoretically appealing. Observations on the effect of neighborhood size (as measured by $|N(x)|$) are inconclusive and appear to problem-dependent [3–5]. Another possibility is to adjust the neighborhood structure with changes in the temperature parameter [1].

For a constrained optimization problem, it may be difficult to generate neighbor solutions that maintain feasibility with respect to one or more constraints. The primary options for applying a local search algorithm to a constrained optimization problem are (i) ensure the generation of feasible neighbors that obey all constraints, or (ii) allow the consideration of infeasible neighbor solutions with a penalization for infeasibility. There are advantages and drawbacks of both approaches. Depending on the nature of the constraint(s), the process of generating only feasible neighbors may be computationally expensive if one cannot develop a procedure to ensure feasibility. In these cases, infeasible neighbor solutions may be discarded or attempts to repair them may be executed through a predefined protocol. Additionally, requiring feasible solutions may degrade the reachability of a neighborhood, retarding SA's ability to search the solution space. However, maintaining feasibility prevents the search potentially wasting time evaluating a large number of infeasible solutions that may not lead to improved feasible solutions. Allowing the consideration of infeasible solutions simplifies the generation of a neighbor solution, but at the cost of increasing the set of candidate solutions to be considered.

Generic Design Features

We consider the design of a cooling schedule to be generic in the sense that it does not explicitly incorporate characteristics of the problem under consideration. The cooling schedule is fully specified by an initial temperature value, number of iterations at each temperature value, cooling function, and final temperature value. With reference to Algorithm 1, the inner while loop (Line 4) controls the number of iterations at each temperature value while the outer while loop (Line 3), in conjunction with the cooling function (Line 18), controls the number and value of different temperature settings. Thus, the cooling schedule governs the stochastic process, a series of finite homogeneous Markov chains, which describes the search path of a SA algorithm.

Initial Temperature. For relatively large values of temperature (τ), SA is essentially a form of random search, as a transition to virtually any neighbor solution is accepted. To capture the benefits of being able to escape local minima and still satisfactorily explore the basins containing them, temperature is typically initiated at a large value and reduced gradually over time. The ideal initial temperature, τ_0 , may vary across problem types (and even across instances of the same problem type), but typically τ_0 is set to a large value so that the final solution is effectively independent of the initial solution. One method to setting τ_0 is to specify a percentage of proposed uphill transitions, χ_0 , to be accepted at the algorithm's onset. Values of χ_0 typically range from 0.80 to 0.99, although if the SA algorithm is seeded with a “good” initial solution and the user wishes to retain the potential benefit of this starting point, χ_0 (and subsequently τ_0) may be set lower in order to restrain the search. The initial temperature is then given by:

$$\tau_0 = \frac{\bar{d}}{\ln(1/\chi_0)},$$

where $\bar{d}$ is an estimate of the average difference in cost of a current solution and its neighbor. Another simple rule is to set $\tau_0 =$

$d_{\max}$, where $d_{\max}$ is an estimate of the largest difference in evaluation function between any two neighboring solutions. Regardless of how τ_0 is estimated, a preliminary number of transitions can be tracked at the onset of the algorithm to ascertain that the percentage of accepted moves surpasses χ_0 ; if τ_0 does not satisfy this threshold, it can be increased and retested.

Iterations per Temperature Value. Theoretical results suggest that the Markov chain generated by the inner loop's set of iterations should be allowed to converge to its stationary distribution before decrementing the temperature. Unfortunately, the number of iterations necessary to even approximate the stationary distribution is exponential in problem size [6]. In practice, the length of the Markov chain at each temperature is usually related to the size of the neighborhood structure or the size of the problem. An alternate approach determines the length of the k^{th} Markov chain by terminating the inner loop if either a minimum threshold of transitions have been accepted or a maximum limit of trials have been attempted. Regardless of the approach, experimental testing is typically required to obtain an effective setting for a wide range of problem instances.

Cooling Function. After employing the search at a fixed temperature for a number of inner loop iterations, the temperature is modified according to a cooling function. Traditionally, the cooling function monotonically decreases the temperature. One basic cooling function is a geometric decrement, that is, $\tau_{k+1} = \alpha \tau_k$, where $0 < \alpha < 1$, with values typically ranging as low as 0.5 and as high as 0.99. Other cooling functions may be designed so that the arithmetic difference between successive temperature settings is constant (rather than the ratio of successive temperature settings).

Many more sophisticated cooling functions exist in the literature, but it is typically advisable to begin with a simple cooling function before moving onto alternatives out of necessity. Empirical evidence suggests that the particular form of cooling schedule is not necessarily relevant as long as the algorithm

spends the appropriate number of iterations over a "critical" temperature range. Rather than strictly adhering to a monotonic cooling schedule, some applications employ the concept of "reheating" in which temperature is increased via an adaptive mechanism that monitors algorithm features such as the number of iterations since last update in best-found solution or the history of accepted and rejected moves, for example, see the sections titled "Job Shop Scheduling Problem" and "Orthogonal Stock-Cutting Problem."

Final Temperature. As temperature approaches zero, SA becomes a descent method in which only transitions to improving neighbor solutions are accepted resulting in convergence to a local minima. There are possible numerous stopping conditions, but the most effective typically triggered when the algorithm's mobility is sufficiently limited. The simplest outer loop termination criteria is to specify a total number of temperature settings to be considered, thereby implicitly defining a final temperature value in conjunction with the cooling function. Placing a ceiling on the amount of computation time also implies a run-time dependent final temperature. Another popular criterion is to terminate the algorithm when the percentage of accepted moves drops below a threshold, χ_f , for a specified number of iterations, and the best overall solution has not been updated recently.

Parameter Calibration

The need for potentially tedious parameter calibration is often a deterrent to successfully implementing SA. To circumvent *ad hoc* parameter-tuning, several researchers have proposed structured parameter calibration approaches based on statistical design of experiments [7–9]. In the development of the algorithm, it is often helpful to track the run-time performance through metrics such as percentage accepted moves, evaluation function of current solution, and evaluation function of best-found solution.

ALGORITHM APPLICATION AND DEVELOPMENT

The past few decades have provided an overwhelming amount of computational experience about the SA algorithm. SA can consistently find high-quality solutions on a wide array of optimization problems, but often at the high cost of computational effort. The remainder of this article highlights some applications of SA (and variants thereof) selected because they demonstrate various innovations in the use of SA that have proven to be empirically competitive with alternate approaches.

Job Shop Scheduling Problem

Van Laarhoven *et al.* [10] apply SA to the job shop scheduling problem (JSP) in which a set of N jobs, each consisting of a sequence of m operations that require execution on a specified series of m machines, must be completed in as little time as possible. For the JSP, a solution can be represented by a set $x = \{\pi_1, \dots, \pi_m\}$, where π_i is a permutation of jobs on machine i . The cost of a solution x is computed by solving a longest-path problem (in $O(N)$ time) for a corresponding directed graph. Thus, the JSP can be reduced to the problem of finding a set of permutations that minimizes the longest path in an appropriately defined directed graph.

Van Laarhoven *et al.* [10] implement a cooling schedule of the form

$$\tau_{k+1} = \frac{\tau_k}{1 + \tau_k \cdot \frac{\ln(1+\delta)}{3\sigma_k}},$$

where δ is a small positive constant (ranging from 0.001 to 1 in the reported experiments) and σ_k is the standard deviation in cost values of the solutions along the search path for the last temperature setting, τ_k . Furthermore, van Laarhoven *et al.* set the number of iterations at each temperature to be equal to the size of the largest neighborhood (over each solution in S).

Van Laarhoven *et al.* [10] define a neighborhood transition in reference to a current solution x ; their neighborhood involves reversing one edge on the longest path and adapting the

adjacent arcs to ensure the generation of feasible candidate solutions. Each solution's neighborhood contains $O(N)$ neighbors and is asymmetric, that is, $y \in N(x) \not\Rightarrow x \in N(y)$.

Motivated by the observation that the asymmetry of standard neighborhoods for the JSP complicates the convergence properties of SA, Kolonko [11] integrates features from genetic algorithms with an annealing approach. Specifically, Kolonko introduces a small population of independent, parallel SA runs in which the “fitness” (adopting the vernacular of genetic algorithms) of an individual SA run in this population is defined by the cost of its best-found solution. After the SA runs are executed for specified number of iterations, they interact via a crossover operation. The crossover operation is applied to the best-found solutions corresponding to randomly selected pairs of SA runs. Relying on a Gantt chart representation, the crossover combines solutions by taking the first portion of the schedule depicted by the first solution and augmenting it the second portion of the schedule depicted by the second solution (with appropriate modifications to ensure feasibility). Repeated application of the crossover operation generates a pool of offspring solutions, which are then used to seed the next generation of SA runs.

Kolonko [11] applies an adaptive control to modify temperature after the consideration of each neighbor solution. If a move from current solution x to candidate solution y is accepted, then the temperature is decreased by an amount depending on whether $c(y)$ is smaller or larger than $c(x)$. If a move from x to y is rejected, the temperature is increased.

SA consistently produces good solutions to the JSP with a modest amount of implementation effort (testing and tuning) and relatively little insight into the combinatorial structure of the problem. However, SA may require large running times, and the computational results are not typically best-in-class.

Traveling Salesman Problem with Time Windows

Ohlmann and Thomas [12] consider SA integrated with a variable penalty method to

allow infeasible solutions in search of near-optimal solutions for the traveling salesman problem with time windows (TSPTW). In the TSPTW, the objective is to find a minimum-cost tour that visits each of n cities exactly once within a city-specific time window. A solution x (a tour through n cities) is represented by an n -permutation and it is evaluated by computing the cost of traversing the tour, $f(x)$, as well as cumulative violation of the time windows, $p(x)$. The cost of a solution x is evaluated as $c(x) = f(x) + \lambda p(x)$, where λ is a scalar penalty multiplier. For a set value of λ , SA can be applied as in Algorithm 1 (with minor changes to account for the storage of the best *feasible* solution in x_{best}).

Determining the value of λ can be a difficult issue. To address the difficulty of determining the appropriate value of the penalty multiplier, Ohlmann *et al.* [13] examine a variant of SA in which the value of λ is initialized at a small value and increased over the course of the algorithm. Within the context of the traveling salesman problem with time windows, Ohlmann and Thomas [12] demonstrate that increasing the penalty multiplier according to a limited-exponential schedule while decreasing temperature according to a geometric schedule outperforms SA executed at various fixed values of λ . Ohlmann and Thomas utilize a one-shift neighborhood, which removes a randomly selected element of the n -permutation and reinserts before another randomly selected element; they discovered that the choice of this neighborhood is critical to the algorithm's effectiveness. Furthermore, Ohlmann and Thomas obtained competitive solutions (best-in-class for some benchmark problems), although typically at the cost of more computation time.

Vehicle-Routing Problems

Bent and van Hentenryck [14] employ SA in a two-phase approach for the vehicle-routing problem with time windows (VRPTW). For a set of customers with known demands and a fleet of vehicles with identical capacities, the VRPTW asks for a set of routes originating from a depot and visiting each customer exactly once within a specified time window. In collectively satisfying the customers' demands, the vehicles' capacities cannot be

exceeded. The vehicle-routing problem (VRP) solutions can be represented as a set of permutations $x = \{\pi_1, \dots, \pi_m\}$, where π_i is the sequence of customers to be visited by vehicle i .

The VRPTW has a hierarchical objective of minimizing the fleet size, and then subject to the minimum fleet size, minimizing the total travel cost of the routes. Bent and van Hentenryck [14] approach the VRPTW with a two-stage algorithm in which the first stage utilizes SA to minimize the number of vehicles, and the second stage uses a large neighborhood search to minimize the total travel cost.

A novel feature of the SA implementation for the first-stage is the "lexicographic" objective function, which guides the search by rewarding solutions that, in order of decreasing importance, (i) minimize the number of routes, (ii) maximize the sum of the squared route cardinalities, and (iii) minimize the minimal delay of the routes. As there are many solutions with the same number of routes, the second and third criteria are effective tie breakers. Maximizing the sum of the squared route cardinalities favors solutions having some routes with many customers and some routes with very few customers over solutions with routes having similar numbers of customers; this aids the minimization of routes since routes with few customers are typically easier to eliminate. For the third criteria, minimal delay is a routing-specific concept that is used to favor solutions such that the smallest route contains customers that can be relocated with the smallest possible violation of capacity or time window constraints (again facilitating route elimination).

Bent and van Hentenryck [14] utilize a neighborhood consisting of five interroute or intraroute operators and consider only feasible neighbors by computationally confirming satisfaction of capacity and time window constraints. At each iteration of the algorithm, a randomly selected operator is applied to a randomly selected customer to construct all feasible candidate solutions in the neighborhood corresponding to the selected operator and customer. Borrowing the concept of aspiration criterion from tabu search, Bent

and van Hentenryck augment the traditional SA approach by first checking to see if the best candidate solution from the constructed neighborhood is better than the best-found solution. If the best candidate solution is better than the best-found-so-far, the algorithm executes the move to this solution; if not, the SA algorithm proceeds by selecting a candidate solution from the constructed neighborhood (incorporating a biased sampling approach in which the likelihood of a solution being selected depends on its objective function value) and then the traditional SA acceptance protocol is applied (Line 13).

The other SA features are standard: a geometric cooling schedule, iteration limit for the inner loop (Line 4), and the combination of a time limit or minimum temperature for the outer loop (Line 3). This two-stage algorithm has proven to be very robust and produces high-quality results across all benchmark VRPTW problems.

Bräysy *et al.* [15] designed a three-phase heuristic for the fleet size and mix vehicle-routing problem with time windows (FSMVRPTW). In the FSMVRPTW, the decision-maker must determine the fleet size and composition (vehicles are heterogeneous with respect to capacity) in addition to the routing of each of the vehicles to collectively visit a set of n customers exactly once within their respective time windows. The first two phases employ problem-specific routing procedures to obtain a good initial solution and then attempt to minimize the fleet size. The final phase of their three-phase heuristic utilizes a deterministic, which replaces the probabilistic transition mechanism of SA with a deterministic rule to determine acceptance or rejection of a neighbor solution. Deterministic annealing aims to achieve the robust search behavior of SA with the efficiency of a deterministic procedure.

Bräysy *et al.*'s deterministic annealing routine mimics an algorithm known as *threshold accepting*. A threshold accepting algorithm substitutes a threshold T in lieu of temperature τ and replaces the condition in Line 13 with $c(y) - c(x) < T$, where T may be controlled in a manner similar to temperature in a SA algorithm. Bräysy *et al.*

[15] decrement T by ΔT units at each nonimproving iteration, and periodically reset T to escape local minima. We note that when generating T from an exponential distribution with a mean equal to τ , threshold accepting becomes equivalent to SA. Another variant of deterministic annealing is *record-to-record travel*. Record-to-record travel substitutes R in place of τ and replaces the condition in Line 13 with $c(y) < Rc(x)$, where R is a user-controlled parameter slightly greater than 1.

Bräysy *et al.* [15] equip their deterministic annealing approach with a compound neighborhood consisting of four different operators, applied in a specified order. The utilization of these intraroute and interroute operators emphasizes the importance of neighborhood choice in designing an effective local search algorithm. Bräysy *et al.* restrict their search solely to feasible solutions. To limit the computation time, Bräysy *et al.* utilize efficient constraint feasibility checks (for the vehicle capacity constraints and time windows) facilitated by sophisticated data structures. In their feasibility tests, they check the capacity constraint first since it is the quickest to calculate, and only proceed to time feasibility if capacity constraints are obeyed.

In addition to the opportunistic constraint-checking, Bräysy *et al.* [15] restrict the neighborhood search to reduce computational effort. Move operations are not applied to routes or route pairs if previous iterations have revealed that improvement is not possible. In addition, moves that introduce solution characteristics unlikely to appear in a near-optimal solution are avoided. To execute this strategy, Bräysy *et al.* prohibit moves that introduce long travel distances into the solution; they employ a learning approach across restarts of the algorithm to vary the definition of a "long" travel distance.

Finally, Bräysy *et al.* [15] incorporate a frequency-based long-term memory (similar to that of tabu search) to facilitate learning of arcs that frequently compose good solutions. This memory is then used to probabilistically generate initial solutions for restarting the algorithm. In summary, the three-phase approach produces excellent results on benchmark problems.

Orthogonal Stock-Cutting Problem

Burke *et al.* [16] embed SA in a two-stage approach for the orthogonal stock-cutting problem (OSCP). In the OSCP, a set of rectangular objects must be placed within the confines of a stock sheet of fixed width so that they do not overlap. The objective is to minimize the required length of the stock sheet under the restriction that objects can only be rotated in 90° increments of their original orientation.

The first stage of the algorithm invokes the best-fit heuristic [17], a tailored placement algorithm for stock-cutting problems, to pack $n - m$ rectangles (from the total set of n rectangles). The second stage packs the remaining m rectangles (not changing the placement of the first $n - m$ rectangles) using an SA algorithm to govern a bottom-left-fill heuristic (another tailored placement heuristic for stock-cutting problems). The solution for this second stage consists of a permutation of rectangle identification numbers. A solution is evaluated by placing the rectangles into the stock sheet in the order denoted by the permutation according to the protocol of the bottom-left-fill heuristic. A neighbor solution is generated by randomly swapping elements of the permutation as well as a probabilistic rotation of first random rectangle involved in the swap. Acceptance or rejection of neighbor solutions is governed by the SA algorithm; a transition from solution x to a worse neighbor solution y is accepted with a probability of $(1 - (c(y) - c(x))/\tau)$ (replacing the traditional acceptance function of Line 13 in Algorithm 1). If a neighbor solution is accepted, temperature is reduced using a geometric multiplier of 0.999. If a neighbor solution is rejected, temperature is increased using a geometric multiplier of 1.0001.

The two-stage approach achieves best-found solutions on a majority of instances, with most solutions at optimal or a few percentage over optimal. Moderate values of m allow the algorithm to couple the benefit of starting with a good partial solution from the best-fit heuristic with a robust annealing-based search. Burke *et al.* [16] note that they also attempted using tabu search and genetic algorithms for the second stage, but simulated annealing outperformed both of these.

FURTHER READING

Noising methods are an approach related to SA. In a noising method, noise is randomly chosen from an interval, which decreases as the algorithm progresses. This noise is added to the objective value, and solutions are then accepted deterministically. Note that a noising method can be viewed as an annealing approach where the randomization is moved from the acceptance probability to the cost evaluation. Alternative methods of managing the noise introduced into the solution evaluation result in variants such as weight annealing [18] and quantum annealing [19].

Consider the class of discrete stochastic optimization problems (DSOPs) in which the objective function values for solutions cannot be evaluated exactly, but rather must be estimated (perhaps via simulation). In this context, noise is not artificially introduced (as in a noising method), but it is inherent in the evaluation due to sampling error. Alrefaei and Andradóttir [20] describe an annealing algorithm for DSOPs that fixes temperature at a constant value. Branke *et al.* [21] study various “stochastic” annealing algorithms for DSOPs, which view the uncertainty in the objective function as analogous to the probabilistic transition mechanism via temperature in a SA algorithm. In stochastic annealing, the probabilistic transition mechanism is transferred from the acceptance criterion into the objective function itself, where sampling an increasing number of neighbor solutions reduces uncertainty in objective function evaluation, analogous to decreasing temperature.

The widespread application of SA is due to the relative ease of implementing its logic, its general nature and flexibility allowing use with little problem-specific tailoring (at least for alpha versions of an implementation), and its robust performance with respect to solution quality and running time on a wide array of problems. The relative simplicity and implementation ease of SA paired with its ability to frequently obtain competitive solutions often make it a method to consider, either as a stand-alone approach, as part of a multistage approach, or hybridized with other heuristic approaches. The algorithmic

implementation suggestions and applications that this article details are just a small sample of the voluminous body of literature related to SA. Other applications in which SA has made a strong impact include time-tabling [22,23], the football pool problem [24], the design of very large scale integrated circuits [25], and image processing [26]. There also exist several variants of simulated annealing for continuous optimization [27,28] and multiobjective optimization [29].

EFFICIENT ITERATIVE COMBINATORIAL AUCTIONS

DEBASIS MISHRA
Indian Statistical Institute,
New Delhi, India

INTRODUCTION

Auctions are a popular way of selling goods—some examples include auctioning of flowers in the Netherlands, auctioning of advertising slots on search engines such as Yahoo! and Google, and auctioning of various goods on eBay. Typically, auctions come in two variants (i) sealed-bid, where bidders submit bids only once and (ii) iterative auctions, which are characterized by monotonic price adjustments given the demands of buyers at every price. Iterative auctions are preferred over their sealed-bid counterparts because of price discovery, decentralized nature, valuation privacy, and better revenue and efficiency properties [1].

Traditionally, auction theory in economics looks at the theory of selling a single indivisible good to multiple buyers [2]. But this changed dramatically with the success of spectrum auctions in the United States, where multiple spectrums were allocated to buyers simultaneously. This also inspired many applications of auctions in which multiple objects were sold simultaneously to buyers—auction of airport landing slots, auction of truckloads in the transportation industry, auction of bus routes in London, and auction of industrial procurement [3]. Such auctions where multiple indivisible objects were sold simultaneously are commonly called *combinatorial auctions* because bidders have values on *bundles* of objects as opposed to individual objects.

Because objects may be either complements or substitutes, the necessity to elicit bids on bundles of objects is clear—for instance, if there is a computer and a keyboard for sale, a bidder may have values 10 and 5, respectively, on each of them, but may have a value of 20 on the bundle of computer and keyboard.

With the success of combinatorial auctions in practice, researchers started investigating research issues in this area. Two strands of literature started—(i) computational, which looked at various computational problems associated with combinatorial auctions and (ii) auction theoretic, which looked at designing combinatorial auctions assuming participants are rational selfish agents. This survey tries to touch on some issues that can be described at the interface of these two strands of literature.

This survey is *not about* “optimal auction design” literature, which asks the question how to design auctions for selling multiple objects so that the expected revenue of the auctioneer is maximized. This problem was addressed by Myerson [4] in his seminal paper for the single object case, but its solution for the multiple object case remains illusive till date. As we explain later, this survey is about designing auctions for selling multiple objects that achieve economic efficiency.

A standard model in auction theory to model the sale of a single indivisible object is that of private values, where each bidder (buyer/agent) has a value, which is his private information, but the seller does not know the value of buyers. The seller would like to sell the object to the highest-valued bidder (economic efficiency). But unless the auction procedure is properly designed, bidders may lie about their value to get more profit. To remedy this, auction theory prescribes the second-price auction, where the good is sold to the bidder with the highest bid but charged a price equal to the second-highest bid. It can be shown that bidding the

true value is a dominant strategy for every bidder.¹

However, this auction is impractical for many reasons [5], and is rarely used in practice. However, its iterative variant (sometimes referred to as the *English auction*) is widely used in practice (for example, Sotheby's auctions, auctions on eBay web site). The auction is iterative and maintains a price in each iteration. It asks buyers if they are willing to buy the good at the current price. If more than one buyer is interested in the good at the current price, then the price is raised. Else, the auction terminates with the only interested buyer winning the good at the current price. Because of its transparency in price discovery, this auction is more practical than the second-price auction, though both the auctions achieve the same outcome in equilibrium.

This inspired researchers to think of the generalization of the English auction for the combinatorial auctions setting. The first such paper was in the mid-1980s, by Demange *et al.* [6] on a specific combinatorial auction setting. We investigate some recent work on the general combinatorial auction setting. We will mainly focus on the works of Mishra and Parkes [7], Bikhchandani and Ostroy [8], Ausubel [9], Parkes and Ungar [10], de Vries *et al.* [11], and Ausubel [12].

The reason for surveying this branch of literature is twofold: (i) the fundamentals of this literature are linear and integer programming, and someone with a good operations research background will enjoy this application; (ii) the motivation of this literature is economic, in the sense that the auctions we will talk about have simple equilibrium bidding strategies for bidders to follow. In the process, we will leave out a large literature on iterative auctions, which

did not consider the economic motivations, and were purely inspired by computational and practical considerations.

Critical to the survey is the presence of strategic agents who are payoff maximizers. What we mean by efficient is that in every state of the world efficiency is achieved. This is possible only by considering the appropriate incentive schemes that are discussed. There are many iterative auctions, which achieve efficiency in the presence of truthful bidders (i.e., bidders are assumed to behave truthfully even in the absence of appropriate incentive schemes), for example, the Clock auctions in Ref. 13. However, we do not treat these as efficient auctions in this survey. The readers are referred to the classic book [14] on this topic.

THE MODEL AND BACKGROUND

The abstract model of the survey is defined in this section. We denote $N = \{1, \dots, n\}$ to be the set of n buyers (bidders/agents) and $M = \{1, \dots, m\}$ to be the set of m indivisible goods. Note that the goods in M can be anything: they can be identical (homogeneous) or heterogeneous or both. Let $\mathbb{S} = \{S : S \subseteq M\}$ be the set of all bundles of goods. Every buyer has a valuation function. The valuation function of buyer i is $v_i : \mathbb{S} \rightarrow \mathbb{R}_+$. The valuation function of buyer i is completely known to buyer i but not known to the seller who is selling the goods. We make the following assumptions about the valuation function.

- *Zero Outside Option.* For every $i \in N$, $v_i(\emptyset) = 0$.
- *Bundle Monotonicity (Free Disposal).* For every $i \in N$ and every $S, T \subseteq \mathbb{S}$ with $S \subseteq T$, we have $v_i(S) \leq v_i(T)$.

Such valuation functions are very general. In particular settings, there are succinct ways to represent a valuation function [15]. We give two such examples below. Let $v : \mathbb{S} \rightarrow \mathbb{R}_+$ be a general valuation function, which satisfies zero outside option and bundle monotonicity.

1. *Unit demand.* A valuation function v is a *unit demand* valuation

¹There is a significant literature in auction theory which considers interdependent valuations [2]. In such a model, every bidder is not sure of his valuations and it depends on the private signals of all the bidders. There are results in this model for simple settings, but not much is known for the multiple object auction case. Interested readers may find Ref. 2 useful.

function if for every $S \in \mathbb{S}$ we have $v(S) = \max_{j \in S} v(\{j\})$. In this case, a buyer is interested in at most one good. So, when presented with a bundle of goods, he picks the one with the highest value amongst those goods. For example, consider a potential buyer is choosing to buy a house amongst a set of houses. Such a valuation function can be very succinctly expressed: every valuation vector can only take m values—one for each good.

2. *Homogeneous Goods.* A valuation function v is a *homogeneous goods* valuation function if for every $S, T \in \mathbb{S}$ with $|S| = |T|$, we have $v(S) = v(T)$. In this case, goods are identical. So, only the size of the bundle dictates the value. Here also, the value function can only take m values, and thus can be succinctly represented.

Below, we give an example to illustrate how valuation functions may look like in a combinatorial auction model. Suppose there are three agents $\{1, 2, 3\}$ and two goods $\{1, 2\}$. A possible valuation profile is shown in Table 1.

There are two parts to the problem: (i) an allocation rule (who should get which bundles) (ii) a payment rule (who should pay how much). While there are many allocation rules possible, the one we discuss here (and which is the center of attention in the literature) is the efficient allocation rule. An allocation $X = (X_0, X_1, \dots, X_n)$ is partitioning of the set of goods where $X_i \in \mathbb{S}$ denotes the bundle allocated to bidder i and X_0 is the unallocated set of goods. Let $\mathbb{X}$ be the set of all allocations. Given a profile of valuation functions $v = (v_1, \dots, v_n)$, an allocation X is efficient if

$$\sum_{i=1}^n v_i(X_i) \geq \sum_{i=1}^n v_i(Y_i) \quad \forall Y \in \mathbb{X}.$$

An efficient allocation rule chooses an efficient allocation for every profile of valuations. Computing an efficient allocation for a given valuation profile is a computationally hard problem [16], but some special cases can be solved easily [17].

A payment rule on the other hand decides how much a bidder pays. If a bidder i has valuation function v_i and he is allocated bundle X_i and pays p_i , then his net utility is given by $v_i(X_i) - p_i$. Such a form of utility function is called the *quasilinear* utility function.

The problem is that the seller has no idea about the valuation functions of the buyer. So, he elicits this information from the buyers in various forms. For example, he may ask the buyers, directly, the valuation function. This is referred to as the *direct* mechanism in auction theory. For many purposes, it is without loss of generality to focus on the direct mechanisms. This is known as the *revelation principle*—for a formal definition of revelation principle, the readers are referred to any standard book in microeconomics, for example, Ref. 18.

However, there is an incentive problem here. The buyer may get higher net utility by lying about his valuation function. For this, the payment and allocation rules need to be designed carefully. Fortunately, for the efficient allocation rule, there is a family of payment functions, which can overcome this incentive problem. These are called the *Groves payment rules* [19]. Suppose $v = (v_1, \dots, v_n)$ is the valuation profile of the buyers. Denote by v_{-i} the valuation profile of buyers other than i . Then, payment of buyer i in a Groves payment rule is given by

$$p_i^G(v) = h_i(v_{-i}) - \sum_{j \neq i} v_j(X_j^*),$$

where X^* is an efficient allocation and h_i is any arbitrary function from valuations of other buyers to real numbers. A particular choice of h_i function stands out. Suppose $h_i(v_{-i}) = \max_X \sum_{j \neq i} v_j(X_j)$. Then the payment

Table 1. Valuations in a Combinatorial Auction

	$\emptyset$	$\{1\}$	$\{2\}$	$\{1, 2\}$
v_1	0	8	9	12
v_2	0	6	8	14
v_3	0	6	5	6

function becomes

$$p_i^{\text{vcg}}(v) = \max_X \sum_{j \neq i} v_j(X_j) - \sum_{j \neq i} v_j(X_j^*).$$

This particular payment rule is popularly known as the *pivotal* payment rule or the *Vickrey–Clarke–Groves (VCG)* payment rule [19–21]. The VCG payment rule along with the efficient allocation rule is called the *VCG mechanism*. Note that the net utility of buyer i in the VCG mechanism is given by

$$\begin{aligned} \pi_i^{\text{vcg}}(v) &= v_i(X_i^*) - p_i^{\text{vcg}}(v) \\ &= \max_X \sum_{j \in N} v_j(X_j) - \max_X \sum_{j \neq i} v_j(X_j). \end{aligned}$$

In other words, every buyer gets a net utility equal to his marginal contribution—the increase in total value of all the buyers when he participates in the auction. In the example in Table 1, the efficient allocation X^* is to allocate good 1 to buyer 1 and good 2 to buyer 2. So the externality of buyer 3 is zero. The externality of buyer 1 is $(8 + 6) - 8 = 6$ and that of buyer 2 is $(9 + 6) - 8 = 7$. Hence, the VCG payments of buyers 1, 2, and 3 are 6, 7, and 0 respectively.

The VCG mechanism is central in economic theory due to various reasons [22]. For example, it satisfies the following properties.

1. *Implements Efficiency.* Every buyer has no incentive to lie about their valuations in the VCG mechanism, that is, bidding truthfully is a dominant strategy.
2. *Individual Rationality.* The VCG mechanism satisfies the property that every buyer has nonnegative net utility. To see this, note that $\max_X \sum_{j \in N} v_j(X_j) \geq \max_X \sum_{j \neq i} v_j(X_j)$, and hence, $\pi_i^{\text{vcg}}(v) \geq 0$.
3. *Losers Pay Nothing.* In the VCG mechanism, if a buyer does not win any bundle, then he pays nothing. This follows from the zero outside option and bundle monotonicity assumptions.
4. *Nonnegative Payments.* Every buyer pays nonnegative amount in the VCG mechanism, that is, no buyer

is awarded or given money. This follows from the fact that $\max_X \sum_{j \neq i} v_j(X_j) \geq \sum_{j \neq i} v_j(X_j^*)$.

However, the VCG mechanism suffers from various practical drawbacks also [5, 14, 23]. We list some below.

1. *Computational.* The VCG mechanism requires one to solve $n + 1$ optimization problems. These optimization problems are computationally hard for arbitrary valuation functions [16].
2. *Communication.* The VCG mechanism requires that every buyer communicates his entire valuation function to the seller. The fact that every buyer's valuation function can have an exponential number of bundle values makes this communication difficult.
3. *Price Discovery and Privacy.* Irrespective of the compelling theoretical property of dominant strategy incentive compatibility, one does not expect buyers to reveal their true values in any mechanism. Privacy of valuations is an important aspect for buyers in practice. Further, the natural process of price discovery is absent in the (sealed-bid) VCG mechanism.

As Ausubel and Milgrom [14] point out, there are some economic issues with the VCG mechanism too—losing bidders have incentives to collude, the outcome in the VCG mechanism is not *stable* and so on. However, these are inherent problems in any Groves mechanism (which implements the efficient allocation rule). For example, Rastegeri *et al.* [24] point out that any Groves mechanism will not be *stable* for a large class of valuation functions. Further, whenever these economic issues are not present for any Groves mechanism, the VCG mechanism is the natural choice for use.

It is difficult to come up with an *algorithm* to overcome the computational and communication overheads of the VCG mechanism. However, algorithms can be designed to implement (achieve) the VCG mechanism, which is more transparent (and respects privacy to some extent) than

the VCG mechanism we just described. These algorithms are precisely the *iterative VCG combinatorial auctions*. Since they implement the same allocation (efficient) and the same payment (VCG) as the VCG mechanism they inherit the incentive properties of the VCG mechanism. One needs some restrictions on the algorithm/iterative auction to inherit the incentive properties of the VCG mechanism [7]. We do not discuss this issue in detail here. In brief, we need some activity rules in the auction to ensure that every bidder bids in a *myopically optimal* manner (as we will see later), and this leads to the VCG outcome. With these activity rules in place, it is also optimal (in a global sense) for every bidder to bid in this manner. We will not discuss the incentive issues in these iterative VCG combinatorial auctions, and assume that bidders are always bidding truthfully. But, we keep in mind that truthful bidding is an equilibrium in these auctions under some mild restrictions on bidding activity.

FOUNDATIONS OF ITERATIVE VCG COMBINATORIAL AUCTIONS

We start by laying the foundations of designing iterative VCG combinatorial auctions. Let us first recall that for the single object case, the Vickrey (second-price) auction has a counterpart in the iterative auction world—the English auction. This auction sheds light on how one can generalize this to the multiple object case. Suppose $v_1 \geq v_2 \geq \dots \geq v_n \geq 0$ be the values of n buyers for the single indivisible good. The English auction starts from a low price (say zero) and asks every buyer if they are interested in the object at this price. If more than one buyer is interested in the good, then the price is increased, and the process is repeated till exactly one buyer is interested. At this point, this buyer wins the good at the current price. It can be shown the buyers have no incentive to lie in this auction, that is, buyers should express interest in the good till the price reaches their respective valuations. Further, if the amount of price increase is low enough, the auction terminates at the second-highest valuation, and

hence implements the same outcome as the Vickrey auction. There are other interesting features of this auction.

1. The buyers see a single price (in $\mathbb{R}_+$), which is increased in every iteration, and this makes the auction very transparent.
2. Call a price a *competitive equilibrium* (CE) price if exactly one buyer demands the object at that price. Any price between v_1 and v_2 is a competitive equilibrium price. Indeed, the auction terminates at the lowest such CE price (ignoring issues of ties). Moreover, such an equilibrium price satisfies the property that if we remove any one of the buyers, this remains an equilibrium price of the new economy as well: v_2 is a CE price of an economy without any buyer. As we will see next, that such pricing is pivotal in designing iterative VCG combinatorial auctions.

Complex Pricing

Unfortunately, for general combinatorial auction models, the simple pricing of the English auction for the single object auction model is not enough. One needs richer prices [7]. These richer and complex prices are essential even without strategic considerations, that is, to simply compute efficiency [25]. We will mainly be concerned with four types of prices.

1. *Linear and Anonymous*. In this pricing, a price is maintained for every good, and every buyer sees the same price. The price of a bundle is the sum of prices of goods in that bundle. Formally, a linear and anonymous price p is a vector in $\mathbb{R}_+^m$, where $p(j)$ indicates the price of good $j \in M$ and price of a bundle of goods S is just $\sum_{j \in S} p(j)$.
2. *Linear and Nonanonymous*. In this pricing, a price is maintained for every good and every buyer, that is, every buyer sees a different linear price vector. Formally, a linear and nonanonymous price p is a vector in $\mathbb{R}_+^{m \times n}$, where $p_i(j)$ indicates the price of good $j \in M$

for buyer i , and price of a bundle of goods S for buyer i is just $\sum_{j \in S} p_i(j)$.

3. *Nonlinear and Anonymous.* In this pricing, a price is maintained for every bundle of good and every buyer sees the same price. Formally, a nonlinear and anonymous price p is a vector in $\mathbb{R}_+^{|\mathbb{S}|}$, where $p(S)$ indicates the price of bundle of goods S .
4. *Nonlinear and Nonanonymous.* This is the most complex of pricing schemes. In this pricing, a price is maintained for every bundle of good and every buyer sees a different price vector. Formally, a nonlinear and nonanonymous price p is a vector in $\mathbb{R}_+^{|\mathbb{S}| \times n}$, where $p_i(S)$ indicates the price of bundle of goods S for buyer i .

Such different types of pricing schemes were first discussed in Ref. 8. As we will discuss, most combinatorial auction models require nonlinear and nonanonymous prices for iterative VCG combinatorial auctions. However, there are instances where simpler prices such as linear and anonymous prices are sufficient to design iterative VCG combinatorial auctions.

Competitive Equilibrium Prices

We will define some notions in this section. These notions are defined for nonlinear and nonanonymous prices, but can be defined for other types of prices as well. From now on, we fix a profile of valuation functions $v = (v_1, \dots, v_n)$. For any price $p \in \mathbb{R}^{|\mathbb{S}| \times n}$, define the (*maximum*) *payoff* of buyer i as

$$\pi_i(p) = \max_{S \in \mathbb{S}} [v_i(S) - p_i(S)]$$

and the *demand set* of buyer i as

$$D_i(p) = \{S \in \mathbb{S} : v_i(S) - p_i(S) = \pi_i(p)\}.$$

Similarly, for any price $p \in \mathbb{R}^{|\mathbb{S}| \times n}$, the *revenue* of the seller is

$$\pi^s(p) = \max_{X \in \mathbb{X}} \sum_{i=1}^n p_i(X_i)$$

and the *supply set* of the seller is

$$F(p) = \left\{ X \in \mathbb{X} : \sum_{i=1}^n p_i(X_i) = \pi^s(p) \right\}.$$

Like in any economic equilibrium, the supply and demand should match. Here, this translates to saying that we can pick bundles in the demand sets of buyers in such a manner that it leads to an allocation in the supply set of the seller.

Definition 1. A price vector p and an allocation X form a *competitive equilibrium* if $X_i \in D_i(p)$ for all $i \in N$ and $X \in F(p)$. If (p, X) is a competitive equilibrium then p is called a competitive equilibrium (CE) price vector.

A CE always exists if the price vector is chosen to be nonlinear and nonanonymous: choose X to be an efficient allocation and p_i to be equal to v_i for all $i \in N$. If price vectors are restricted to be linear and anonymous, then a CE exists under a condition called *gross substitutes* [26,27]. The gross substitutes condition requires goods to be substitutes of each other. This condition is satisfied for unit demand valuations and for homogeneous goods valuations if the marginal value of a unit is nonincreasing.

If (p, X) is a CE, then X is an efficient allocation. This fact can be shown by formulating the problem of finding an efficient allocation as a linear program. To do so, define for every $i \in N$ and every $S \in \mathbb{S}$ a binary variable $x_i(S) \in \{0, 1\}$, where $x_i(S) = 1$ indicates that buyer i gets bundle S and $x_i(S) = 0$ indicates that buyer i does not get bundle S . Also, define a binary variable $z(X) \in \{0, 1\}$ for every $X \in \mathbb{X}$, which indicates if allocation X is chosen or not. Then, the problem of finding an efficient allocation can be formulated as follows [8].

$$\begin{aligned} V(N) = \max_{x, z} & \sum_{i=1}^n \sum_{S \in \mathbb{S}} v_i(S) x_i(S) \\ \text{s.t.} & \end{aligned} \tag{1}$$

$$\begin{aligned}
\sum_{S \in \mathbb{S}} x_i(S) &= 1 \quad \forall i \in N \\
\sum_{X \in \mathbb{X}} z(X) &= 1 \\
x_i(S) &= \sum_{X \in \mathbb{X}: X_i = S} z(X) \quad \forall i \in N, \forall S \in \mathbb{S} \\
x_i(S) &\in \{0, 1\} \quad \forall i \in N, \forall S \in \mathbb{S} \\
z(X) &\in \{0, 1\} \quad \forall X \in \mathbb{X}.
\end{aligned}$$

It is easy to see that Equation (1) finds an efficient allocation. The constraints of Equation (1) ensure that an allocation is chosen and the objective function maximizes the total value of buyers over all allocation. As we will show later, there is another simpler formulation possible than formulation (1)—see formulation (5). However, formulation (1) has some nice features as we discuss below.

The linear programming relaxation of Equation (1) admits integer solution [8]. Hence, the problem of finding an efficient allocation reduces to the following linear program.

$$\begin{aligned}
V(N) &= \max_{x, z} \sum_{i=1}^n \sum_{S \in \mathbb{S}} v_i(S) x_i(S) \\
\text{s.t.} \quad & \\
\sum_{S \in \mathbb{S}} x_i(S) &= 1 \quad \forall i \in N \\
\sum_{X \in \mathbb{X}} z(X) &= 1 \\
x_i(S) &= \sum_{X \in \mathbb{X}: X_i = S} z(X) \quad \forall i \in N, \forall S \in \mathbb{S} \\
x_i(S) &\geq 0 \quad \forall i \in N, \forall S \in \mathbb{S} \\
z(X) &\geq 0 \quad \forall X \in \mathbb{X}.
\end{aligned} \tag{2}$$

This linear program has an exponential (in number of goods and buyers) number of variables and constraints. So, in practice, it is not useful. However, it serves as an ideal tool to design an iterative VCG combinatorial auction. For this, it is useful to look at its dual given below.

$$\begin{aligned}
V(N) &= \min_{p, \pi, \pi^s} \sum_{i \in N} \pi_i + \pi^s \\
\text{s.t.} \quad & \\
p_i(S) + \pi_i &\geq v_i(S) \quad \forall i \in N, \forall S \in \mathbb{S} \\
\pi^s - \sum_{i \in N} p_i(X_i) &\geq 0 \quad \forall X \in \mathbb{X}
\end{aligned} \tag{3}$$

The interpretation of the dual variables are clear: p is the price vector, π is the payoff vector of buyers, and π^s is the revenue of the seller. The following result establishes the connection between CE and these formulations.

Theorem 1 [8]. *A pair (p, X) is a competitive equilibrium if and only if X corresponds to the optimal solution of Linear Program (2) and p corresponds to the optimal solution of Linear Program (3).*

The proof of this result involves writing down the complementary slackness conditions and showing their equivalence to the CE conditions. A consequence of this result is that finding an efficient allocation is equivalent to finding a CE price vector. Of course, a CE price vector may be an exponential (in number of goods) sized vector. But the theorem also works in settings where simpler (anonymous and linear) CE price vectors exist. For example, in unit-demand settings, anonymous and linear CE price vectors exist, and finding, there, an efficient allocation is equivalent to finding such a CE price vector.

The foundations of iterative auctions are CE price vectors, in the sense that every iterative auction (appropriately defined) searches for a CE price vector, and finds an efficient allocation. However, the incentive properties of the VCG mechanism is not inherited by every CE price vector. As we will show next, there is a large class of CE prices from which VCG payments can be deduced. However, there are CE price vectors that correspond directly to the VCG payments if a condition on a valuation function is satisfied. We discuss two such conditions. For every $K \subseteq N$, let $V(K)$ denote the objective function value of the optimal solution of Equation (2), when Equation (2) is solved by considering agents in K only.

Definition 2 *Agents are substitutes if $V(N) - V(K) \geq \sum_{j \in N \setminus K} [V(N) - V(N \setminus \{j\})]$ for all $K \subseteq N$. Agents are submodular if $V(T) - V(T \setminus \{j\}) \geq V(K) - V(K \setminus \{j\})$ for all $T \subseteq K \subseteq N$ and for all $j \in N$.*

It is easy to see that if agents are submodular, then agents are substitutes. However, the converse is not true (Ref. 7 contains examples).

We say that a CE price vector is *minimal* if it is a solution to the following linear program (4).

$$\begin{aligned} \Pi^{\max} &= \max_{p, \pi, \pi^s} \sum_{i \in N} \pi_i \\ \text{s.t.} \quad & \\ & \sum_{i \in N} \pi_i + \pi^s = V(N) \\ & p_i(S) + \pi_i \geq v_i(S) \quad \forall i \in N, \forall S \in \mathbb{S} \\ & \pi^s - \sum_{i \in N} p_i(X_i) \geq 0 \quad \forall X \in \mathbb{X} \end{aligned} \quad (4)$$

Formulation (4) finds a CE price vector, which gives the maximum total payoff to agents over all CE price vectors. By maximizing the total payoff to agents, we also minimize their total payments over all CE price vectors. This results in finding the minimal CE price vector.

Theorem 2 [8]. *Agents are substitutes if and only if for every $i \in N$ we have*

$$p_i^{\text{vcg}}(v) = p_i^{\min}(X_i),$$

where $p^{\min}$ is an optimal solution of Linear Program (4) and X corresponds to an optimal solution of Linear Program (2) that is, $p^{\min}$ is a minimal CE price vector and X is an efficient allocation.

In general, the VCG mechanism requires one to solve the linear program (2) $n + 1$ times. The implication of this theorem is that under the agents are substitutes condition, one needs to solve only the linear programs (2) and (4) to find the outcomes of the VCG mechanism. The agents are substitutes condition is satisfied if goods are somewhat substitutes (and not complements). For example,

it is satisfied in the unit demand case and in the homogeneous goods case if the marginal value of a unit is nonincreasing for buyers.

It is worth commenting that there is an integer programming formulation of (2). Let $x_i(S) \in \{0, 1\}$ denote if agent i gets bundle S or not. Then an alternative formulation of finding an efficient allocation is as follows.

$$\begin{aligned} V(N) &= \max_x \sum_{i \in N} \sum_{S \in \mathbb{S}} v_i(S) x_i(S) \\ \text{s.t.} \quad & \\ & \sum_{i \in N} \sum_{S \in \mathbb{S}: j \in S} x_i(S) \leq 1 \quad \forall j \in M \\ & \sum_{S \in \mathbb{S}} x_i(S) = 1 \quad \forall i \in N \\ & x_i(S) \in \{0, 1\} \quad \forall i \in N, \forall S \in \mathbb{S}. \end{aligned} \quad (5)$$

The constraints in Equation (5) ensures that no object is assigned to more than one buyer and every agent is assigned to exactly one bundle (possibly the empty bundle). The objective function maximizes the total value from the allocation specified by the feasibility constraints. Though this is an integer programming formulation of the efficient allocation problem, it involves fewer number of constraints and variables than formulation (2).

Theorem 2 is silent on two accounts with regard to the power of CE price vectors in terms of extracting the VCG mechanism information: (i) it does not say how *informative* nonminimal CE price vectors can be; (ii) it does not say what happens when the agents are substitutes condition does not hold. These two difficulties can be overcome by generalizing the notion of CE prices.

Universal Competitive Equilibrium Prices

We introduce the notion of universal competitive equilibrium (UCE) prices. It is a useful concept to analyze and design iterative VCG auctions. For any nonlinear and nonanonymous price vector p , for every $K \subseteq N$ ($K \neq \emptyset$) let p^K denote the restriction of price vector p to the set of agents K . Define for every $i \in N$, $N_{-i} = N \setminus \{i\}$ and $\mathbb{N} = N \cup_{i \in N} N_{-i}$. An *economy* is defined by a set of agents N , a

set of goods M , and the valuation functions $v \equiv \{v_i\}_{i \in N}$ of agents.

Definition 3. A competitive equilibrium price vector p of economy (N, M, v) is a *universal competitive equilibrium (UCE)* price vector of this economy if p^K is a competitive equilibrium price vector for economy $(K, M, \{v_i\}_{i \in K})$ for every $K \in \mathbb{N}$.

Note that the definition does not require the price vector to be nonlinear and nonanonymous. A UCE price vector can be defined for any type of price vector. Similarly, the result we state relating the UCE price vector to the VCG mechanism is independent of the type of UCE price vector (i.e., the representation of the UCE price vector). A nonlinear and nonanonymous UCE price vector always exists: let $p_i := v_i$ for all $i \in N$.

We give three examples of UCE prices below. We note that anonymous and linear UCE prices are available in the first two examples below.

1. *Single Good.* In the single indivisible good case, there is a unique anonymous UCE price. Take an example with four buyers with values 10, 8, 6, 4 for the good. Then, any price in $[8, 10]$ is an anonymous CE price. However, the price 8 is the unique anonymous UCE price. To see this, note that 8 continues to be a CE price even if we remove any one of the buyers from the economy. As we know, 8 is also the price paid by the highest bidder in the second-price Vickrey auction.
2. *Unit Demand.* In the unit demand valuation case, there is a unique linear and anonymous UCE price vector [28]. Consider an example with two goods and three buyers. The valuations of the buyers on goods are given as follows: $v_1(1) = 5, v_1(2) = 3, v_2(1) = 3, v_2(2) = 4, v_3(1) = 2, v_3(2) = 2$. Since this is a unit demand setting, the valuations of buyers on bundles can be derived from this. It is easy to verify that the unique efficient allocation for this example is buyer 1 gets good 1 and buyer 2 gets

Table 2. Valuations in a Combinatorial Auction

	$\emptyset$	$\{1\}$	$\{2\}$	$\{1, 2\}$
v_1	0	3	0	3
v_2	0	0	6	6
v_3	0	0	2	4

good 2. The unique linear and anonymous UCE price vector is $(2, 2)$. At this price vector, the demand set of buyer 3 includes all possible bundles of goods, including $\emptyset$. The demand set of buyer 1 consists of good 1 and that of buyer 2 consists of good 2. Using these facts, one can easily verify that $(2, 2)$ is a linear and anonymous UCE price vector.

3. *General Valuation.* Consider the example in Table 2 with three buyers and two goods. Consider the following nonlinear and nonanonymous price vector for this example: $p_1(\{1\}) = 2 = p_1(\{1, 2\})$, $p_1(\{2\}) = 0$, $p_2(\{1\}) = 0$, $p_2(\{2\}) = 4 = p_2(\{1, 2\})$, $p_3(\{1\}) = 0$, $p_3(\{2\}) = 2$, $p_3(\{1, 2\}) = 4$. The efficient allocation for this example is buyer 1 gets good 1 and buyer 2 gets good 2. The reader can verify that this is a UCE price vector.

The following important theorem illustrates the relationship between UCE price vectors and VCG payments.

Theorem 3 [7]. Suppose (p, X) is a CE of economy (N, M, v) . The VCG payments of agents in this economy can be computed from (p, X) if and only if p is a UCE price vector of this economy. Moreover, if p is a UCE price vector then for every $i \in N$,

$$p_i^{\text{VCG}}(v) = p_i(X_i) - [\pi^s(p) - \pi^s(p^{N-i})].$$

This result says that UCE prices (with an efficient allocation) are necessary and sufficient for computing VCG payments from CE prices and efficient allocation. Moreover, it says that the bidders need to be given discounts from their CE prices to obtain VCG payments. Note that these discounts are zero if the UCE price vector is anonymous—this

is the case for single good setting and the unit demand setting, where anonymous UCE price vectors are known to exist.

For the example in Table 2, a UCE price vector p is

$$\begin{aligned} p_1(\{1\}) &= 2 = p_1(\{1, 2\}), p_1(\{2\}) = 0 \\ p_2(\{1\}) &= 0, p_2(\{2\}) = p_2(\{1, 2\}) = 4 \\ p_3(\{1\}) &= 0, p_3(\{2\}) = 2, p_3(\{1, 2\}) = 4. \end{aligned}$$

The efficient allocation for this example is to allocate good 1 to buyer 1 and good 2 to buyer 2. We can compute $\pi^s(p) = 6$, $\pi^s(p^{N-1}) = 4$, $\pi^s(p^{N-2}) = 4$, $\pi^s(p^{N-3}) = 6$. Hence, the discounts of buyers 1, 2, and 3 are respectively, 2, 2, and 0. So, the VCG payments of buyers 1, 2, and 3 are $2 - 2 = 0$, $4 - 2 = 2$, and 0 respectively.

The result in Theorem 3 also gives hints on how to achieve the outcome of the VCG mechanism using CE prices—we need to search for UCE prices. Mishra and Parkes [7] give a class of auctions using nonlinear and nonanonymous prices for general valuations of bidders, which search for UCE prices and achieve the VCG outcome. We revisit one of the auctions.

iBundle—EXTEND AND ADJUST (iBEA) AUCTION

We present an iterative auction for general valuations of combinatorial auctions. The auction is an extension of the iBundle auction in Ref. 10 and the auction in Ref. 9. This description follows along the lines of Ref. 7.

In every iteration of the auction, a nonlinear and nonanonymous price vector is maintained. Denote such a price vector in round t of this auction as p^t . Given such a price vector, the building block of the auction is to solve an integer programming problem, commonly referred to as the *winner determination problem* (WDP).

The Winner Determination Problem

In this section, we formalize the WDP. In a WDP, we are given a nonlinear and nonanonymous price vector $p \in \mathbb{R}_+^{n \times |S|}$ and

the demand sets of buyers at this price vector. The objective is to determine an allocation that *maximizes* the revenue of the seller at this price such that every buyer is either assigned a bundle from his demand set or the $\emptyset$ bundle, that is, find an allocation X at price vector p , such that $\pi^s(p) = \sum_{i \in N} p_i(X_i)$ subject to $X_i \in D_i(p) \cup \{\emptyset\}$. This problem can be formulated as an integer program as follows. Let $x_i(S) \in \{0, 1\}$ denote whether agent i is allocated a bundle $S \in D_i(p) \cup \{\emptyset\}$. The following integer program solves the WDP at price vector p .

$$\begin{aligned} \pi^s(p) &= \max_x \sum_{i \in N} \sum_{S \in D_i(p) \cup \{\emptyset\}} p_i(S) x_i(S) \\ \text{s.t.} & \\ \sum_{i \in N} \sum_{S \in D_i(p) \cup \{\emptyset\}} x_i(S) &\leq 1 \quad \forall j \in M \\ \sum_{S \in D_i(p) \cup \{\emptyset\}} x_i(S) &= 1 \quad \forall i \in N \\ x_i(S) &\in \{0, 1\} \quad \forall i \in N, \forall S \in D_i(p) \cup \{\emptyset\}. \end{aligned} \tag{6}$$

The constraints of formulation (6) ensure that every agent is assigned either a bundle from his demand set or the empty bundle, and every good is assigned to at most one agent. The objective function ensures that we choose an allocation that maximizes the revenue to the seller at this price vector. It is worth noting that formulation (6) becomes equivalent to formulation (5) if the price vector is the same as the valuation vector.

An extensive literature exists on the computational aspects of the WDP—a good reference is Ref. 17. We want to note here that the WDP, in general, is NP-hard to solve, but some tractable instances exist [16, 17].

In the auction we discuss next, we will solve instances of WDP for any economy $K \in \mathbb{N}$. We will therefore denote WDP^K to denote the winner determination problem of economy with agents $K \in \mathbb{N}$. We denote the allocation chosen by the WDP^K at price vector p^K as $X^{p,K}$, and call it an *optimal allocation* at p^K . Let $L(p, K) = \{i \in K : X_i^{p,K} = \emptyset \text{ and } \emptyset \notin D_i(p^K)\}$ be the set of agents who do not get any bundle in the WDP^K and their demand sets do not contain the $\emptyset$. We call such agents

unsatisfied agents at price vector p . The revenue of the seller from the WDP of economy with agents K at price vector p will be denoted as $\pi^s(p^K)$ —it is the value of the optimal solution of Equation (6) at price vector p^K for economy with agents K .

Description of the iBEA Auction

For simplicity of description and analysis, we assume that the valuations of agents are integers. However, the ideas of the auction extends to arbitrary real-valued valuation functions. Assuming any real valuation brings additional convergence problems due to bid increments, which require cumbersome analysis techniques. These problems disappear if one assumes integer valuations.

The iBEA auction orders the elements of the set $\mathbb{N}$. Suppose the ordering is N , followed by N_{-1} , followed by $N_{-2}, \dots, N_{-n}$. Denote $N \equiv N_{-0}$.

iBEA AUCTION

- S0 Initiate the round number $t = 0$ and let p^0 be the zero price vector.
- S1 For $i = 0, 1, \dots, n$
 - S1.1 Ask demand sets of buyers at price vector p^t .
 - S1.2 Solve $\text{WDP}^{N_{-i}}$ at price vector p^t (restricted to N_{-i}).
 - S1.3 If $L(p^t, N_{-i}) = \emptyset$ (i.e., no unsatisfied agents), then $i = i + 1$ and repeat from Step S1 with $p^{t+1} = p^t$ and $t = t + 1$.
 - S1.4 If $L(p^t, N_{-i}) \neq \emptyset$, then set $p_j^{t+1}(S) = p_j^t(S) + 1$ for all $j \in L(p^t, N_{-i})$ and for all $S \in D_j(p^t)$. Repeat from Step S1.1 with $t = t + 1$.
- S2 Let X be the allocation chosen by $\text{WDP}^{N_{-0}}$ in the final round when $i = 0$. Let the final price vector in the auction be p . Then, the final allocation of the auction is X and payment of agent j is $p_j(X_j) - [\pi^s(p) - \pi^s(p^{N_{-j}})]$ (discounts from the terminating prices).

The iBEA auction searches for a UCE price vector, and as we will show next, it terminates at a UCE price vector. We illustrate the auction with an example in Table 3.

The last columns indicate seller's revenue in economy N (main economy) and *marginal economies* (economies with agents N_{-1}, N_{-2} , and N_{-3} respectively). Prices in parenthesis for a buyer and a bundle indicate that such a bundle is in the demand set of the respective buyer at that price. We see in Table 3 that iBEA solves the WDP of main and marginal economies in every round and terminates at a UCE price vector. Discounts are then calculated for every bidder to compute the VCG payments.

We say that the iBEA auction *terminates after the main economy* if the auction does not see any price increase for $i > 0$ in Step S1, that is, we reach a UCE price vector after finding a CE price vector of economy with all the agents. The main result is that this auction terminates with a UCE price vector and achieves the VCG outcome. However, under a variety of conditions, it terminates as soon as a CE price vector of main economy (economy with all the agents) is discovered.

Theorem 4. *Suppose agents submit their demand sets truthfully in an iBEA auction. Then, the following statements are true.*

1. *The iBEA auction terminates at a UCE price vector and the outcome is the same as that of the VCG mechanism [7].*
2. *If the agents are substitutes condition holds, then the iBEA auction terminates after the main economy with the VCG outcome [7].*
3. *If the agents are submodular condition holds, then the iBEA auction terminates after the main economy with the VCG outcome, and the discount given to every agent is zero [7,9].*

CONCLUDING REMARKS

1) General Class of Ascending Auctions. Mishra and Parkes [7] discuss a more general class of ascending auctions for general valuation functions. This class contains the iBEA auction and generalizations of auctions in Ref. 11. Results (1) and (2) in Theorem 4 hold for any auction in this general class.

Table 3. Progress of *i*BEA for an Example

Values	Buyer 1			Buyer 2			Buyer 3			Seller revenue in main and marginal economies
	{1}	{2}	{1, 2}	{1}	{2}	{1, 2}	{1}	{2}	{1, 2}	
	3	0	3	0	6	6	0	2	4	
1	(0)	0	(0)	0	(0)	(0)	0	0	(0)	{0,0,0,0}
	WDP of N . WDP selects allocation $\{\{1\}, \{2\}, \emptyset\}$. Buyer {3} is unsatisfied.									
2	(0)	0	(0)	0	(0)	(0)	0	0	(1)	{1,1,1,0}
	WDP of N . WDP selects $\{\emptyset, \emptyset, \{1, 2\}\}$. Buyers {1, 2} are unsatisfied.									
3	(1)	0	(1)	0	(1)	(1)	0	0	(1)	{2,1,1,2}
	WDP of N . WDP selects $\{\{1\}, \{2\}, \emptyset\}$. Buyer {3} is unsatisfied.									
4	(1)	0	(1)	0	(1)	(1)	0	(0)	(2)	{2,2,2,2}
	WDP of N . WDP selects $\{\{1\}, \{2\}, \emptyset\}$. Buyer {3} is unsatisfied.									
5	(1)	0	(1)	0	(1)	(1)	0	(1)	(3)	{3,3,3,2}
	WDP of N . WDP selects $\{\emptyset, \emptyset, \{1, 2\}\}$. Buyers {1, 2} are unsatisfied.									
6	(2)	0	(2)	0	(2)	(2)	(0)	(1)	(3)	{4,3,3,4}
	WDP of N . WDP selects $\{\{1\}, \{2\}, \emptyset\}$. Buyer {3} is unsatisfied.									
7	(2)	0	(2)	0	(2)	(2)	(0)	(2)	(4)	{4,4,4,4}
	CEs of economies with agents N , N_{-2} , and N_{-3} are reached. $\{\{1\}, \{2\}, \emptyset\}$ is an efficient allocation. WDP of N_{-1} . WDP selects $\{\emptyset, \emptyset, \{1, 2\}\}$. Buyer {2} is unsatisfied.									
8	(2)	0	(2)	0	(3)	(3)	(0)	(2)	(4)	{5,4,4,5}
	WDP of N_{-1} . WDP selects $\{\emptyset, \emptyset, \{1, 2\}\}$. Buyer {2} is unsatisfied.									
9	(2)	0	(2)	0	(4)	(4)	(0)	(2)	(4)	{6,4,4,6}
	A UCE price is reached. Final allocation: $\{\{1\}, \{2\}, \emptyset\}$. Final payment: $p_1(\{1\}) = 2 - [6 - 4] = 0$, $p_2(\{2\}) = 4 - [6 - 4] = 2$, $p_3(\emptyset) = 0$.									

Result (3) holds for *i*BEA auction and the auction in Ref. 11. These auctions can be interpreted to be solving the linear program (2) using a primal dual algorithm. This connection is established explicitly in Ref. 11; also see Refs 10 and 29.

2) Experimental Evidence. In a recent paper, Chen and Takeuchi [30] investigate how the *i*BEA auction performs in practice. They conduct experiments and compare its performance against the sealed-bid VCG auction. The experiment uses humans and robots to study these two auction formats. The main finding of this study is that while the sealed-bid VCG auction achieves greater revenue for the seller, the *i*BEA auction achieves greater bidder profit and efficiency. Further, the *i*BEA auction achieves 100% efficiency in significantly large instances than the sealed-bid VCG auction. This substantiates the use of *i*BEA over its sealed-bid counterpart.

3) Simpler Prices. In general, the *i*BEA auction requires complex nonlinear and

nonanonymous prices. Such complex prices are necessary for general valuations, as we have argued earlier. For simple valuation functions, one may do away with such complex prices. We discuss two such valuation functions.

One is the case of unit demand valuations. There exist ascending auctions, which achieve the VCG outcome using anonymous and linear prices [6].

The other is the case of *homogeneous goods with nonincreasing marginal valuations (NIMV)*. In such a case, the goods are homogeneous, but the marginal value of a unit is nonincreasing for every buyer. In this case, an ascending auction with simple prices exists, which achieves the VCG outcome [12]. This auction implicitly maintains nonlinear and nonanonymous prices [31]. These nonlinear and nonanonymous prices find a succinct representation in this case. It is an *open question* if such auctions with simple prices is

possible in any other interesting valuation functions.

4) Descending Auctions. One wonders if the ascending price trajectories can be replaced by descending ones in these auctions. The answer is not trivial as the search for a UCE price vector has to be done carefully, specially if we have auctions, which use simpler prices. Mishra and Parkes [28] demonstrate that the UCE price concept can be used to design descending price auction counterparts of the auctions in Refs 6 and 12 for unit demand and homogeneous good NIMV settings respectively. These descending auctions maintain simple prices and achieve the VCG outcome. With complex nonlinear and nonanonymous prices, the descending auction counterpart of the *i*BEA auction can be found in Ref. 32. However, this auction has the undesirable feature of terminating at “price=value” (i.e., $p_i(S) = v_i(S)$ for all $i \in N$ and for all $S \in \mathbb{S}$) UCE price vector often. It is an *open question* to design descending auction counterpart of the *i*BEA auction for special cases of valuation functions with simpler prices.

Auctions for Complements. Though the *i*BEA achieves the VCG outcome for general valuations, one needs to run the *i*BEA auction even after achieving the CE price vector of the main economy if agents are substitutes condition does not hold. This is an undesirable feature since in the *i*BEA rounds for $i \neq 0$ in Step S1, the demand sets of bidder i is not used in the auction. Further, the bids of bidders in N_{-i} is only used to compute the payment of bidder i . These undesirable features are present if the agents are substitutes condition does not hold.

The agents are substitutes condition almost implies that goods are substitutes and not complements [8,9]. It is an *open question* as to how to design iterative auctions, which avoid this problem of *i*BEA when goods are complements. A conjecture is that it may be an auction, which is a mixture of ascending and descending prices.

Acknowledgments

I am indebted to David Parkes, with whom I did most of my work on combinatorial auctions, for being a wonderful coauthor and an

even more wonderful friend and person. This survey is dedicated to David. I acknowledge support from Planning and Policy Research Unit (PPRU) at ISI, Delhi.

EFFICIENT USE OF MATERIALS AND ENERGY

VALERIE M. THOMAS

Technology, Atlanta, Georgia

THE LINKAGE OF ENERGY, MATERIALS, AND ECONOMIC DEVELOPMENT

Worldwide, economic development has been closely tied to increases in energy and material consumption; in many countries a strong correlation has been observed between economic growth and growth in energy consumption. Material use has also risen in line with economic growth and energy use. Some developed economies are significantly more efficient than others in terms of gross domestic product (GDP) per unit of energy consumption, as illustrated in Fig. 1. Moreover, a number of economies are showing increased energy efficiency, with energy use rising less fast than economic production, as illustrated in Fig. 2 for the United States.

From a technological perspective, there is considerable potential for increased energy and material efficiency. The conversion of fuels into electricity, motion, light, and other services is markedly inefficient [1], as illustrated in Table 1. Energy end-use efficiency could be considerably improved with better designs of buildings, products and services, and transportation systems. Material use is perhaps even less efficient. On average, Americans dispose of about 2 kg of municipal waste per person per day; Europeans, on average, dispose of about 1.5 kg per person per day. Although industrial waste production is not well measured, the quantity is at least several times greater than municipal waste. With costs of disposal being relatively low, there has been little incentive to increase material efficiency.

ENERGY AND ENVIRONMENTAL IMPACTS FROM A COMPANY PERSPECTIVE

Through the 1980s, energy and environmental policy and research focused on industrial emissions and specific highly polluting activities. Legislation focused on emissions from power plants and large industrial facilities, and on specific types of emissions such as pesticides, heavy metals, oxides of sulfur and nitrogen, and particulate matter. To some extent, because of progress in reducing the most acute emissions and impacts, and to an even greater extent as the comprehensive nature of energy and environmental challenges became more clear, underlying issues of the environmental impacts of products and their entire life-cycle supply chains have come to the fore [2,3]. While existing legislation focuses on specific pollutants from a risk framework, the focus of environmental analysis has shifted to a comprehensive view of product systems.

To make processes, products, and material management more efficient and environmentally benign requires extensive redesign of processes and products [4]. A framework for environmental design requires evaluation of the environmental implications of different choices of materials, product design, production processes, and service format as well as choices regarding recycling, repair, and disposal.

Life Cycle Assessment

Environmental life-cycle assessment (LCA) is the method by which the environmental impacts of different products or activities can be compared on a systematic basis (see ***Closed-Loop Supply Chains: Environmental Impact***). It is the analytical foundation of many environmental design tools. In principle, an LCA evaluates the entire environmental impact of a product through its life cycle, including manufacturing, use, and disposal. Supply chain models that incorporate environmental life-cycle assessment are

Figure 1. The ratio of gross domestic product (GDP) to total primary energy consumption for a selection of developed countries, shown with respect to GDP per person in each country. Data are for 2006, and GDP is calculated using purchasing power parities. [Source: US Department of Energy, Energy Information Administration, 2008. International Energy Annual 2006].

Figure 2. US GDP and total primary energy consumption from 1949 to 2008. [Source: US Department of Energy, Energy Information Administration, 2009. Annual Energy Review 2008].

beginning to provide a basis for evaluating supply chains in terms of a range of environmental impacts as well as cost [5]. Life-cycle assessments of supply chains typically find that industrial and agricultural operations have greater energy and greenhouse gas impact than transportation, although transportation typically is the main use of petroleum in a supply chain. Within the

transportation sector, air transport has considerably greater energy intensity than truck freight, which has significantly greater energy intensity than rail freight, and thus mode shifting from air to truck or from truck to rail can considerably reduce the petroleum consumption of a supply chain.

Policies to limit greenhouse gas emissions could have a significant impact on supply

Table 1. Efficiency of Energy Conversion Technologies.

Conversion Technology	Efficiency (%)	Physical Limitations
Gas and steam turbines	46	Thermodynamics
Internal combustion engines	40	Thermodynamics
Fuel cells	70	Electrode, electrolyte, catalysts
Solar photovoltaics	41	Band gap, crystalline structure
Wind turbines	59	Betz limit
Incandescent lamps	5	Blackbody spectrum
Fluorescent lamps	20	Phosphors, ballasts

Efficiency percentages refer to achieved, predicted, or maximum theoretical limits, and are in some cases subject to change as technology develops.

chain management. Coal and electricity prices are generally more sensitive to the cost of carbon dioxide emissions, and thus a price on greenhouse gas emissions is likely to increase the cost of electricity and coal more substantially than the cost of petroleum. Consequently, supply chain management could begin to favor low-greenhouse gas manufacturing, even if supply chain transport distances increase.

There is considerable scientific understanding of the environmental and health impacts of industrial pollutants, and of a range of industrial and human activities. However, most products have more than one type of environmental impact, and these impacts are usually incommensurate. There are ecosystem impacts, and there are human health impacts. There are varying levels of uncertainty associated with different environmental impacts. There are different types of human health impacts, including acute toxicity, carcinogenicity, and developmental toxicity, that affect different groups of people differently. Some environmental impacts can be compared on a strictly scientific basis, but for many others, a judgment must be made about their relative importance. To integrate across diverse dimensions of environmental

performance, a number of weighted environmental metrics have been developed. For example, a scoring system called *eco-indicator* is designed as a measure of overall environmental impact; human toxicity potential has been developed as a measure of the toxicity of chemical compounds over a range of human health end points [6]. Willingness-to-pay has been developed as an economic measure of environmental health impacts, and quality adjusted life years (QALYs) have been developed as a measure of health outcomes [7]. While a number of software packages provide integration over different environmental impacts, it is also common practice not to aggregate over different types of environmental impacts because the scientific basis for aggregation is not established.

Environmental Management Strategies

While traditional command-and-control environmental policy aims to reduce pollution by setting a cap on emissions or by requiring pollution control devices, some new environmental strategies aim for economically efficient environmental protection. These strategies are related to the efficiency movement in management, with its emphasis on eliminating waste, and could be viewed as part of an overall lean business strategy. Markets for pollutants have been successfully developed to reduce SO₂ emissions in the United States at low cost. Mandatory carbon dioxide markets have been established in the European Union and as of 2009, they were under serious consideration for a national policy in the United States. Other new environmental strategies aim to promote innovation, not simply by controlling emissions but by encouraging the development of processes and product designs that are inherently clean.

It has been suggested that by selling a service rather than a product, firms and consumers could have an incentive to be more efficient with materials and energy. For example, an integrated pest management service might provide crop protection rather than selling pesticides per se. Some efforts to implement this strategy have failed to take hold, with carpet leasing a notable example,

whereas car sharing is seeing commercial success [8].

Another approach is to provide consumers with environmental information about products. Many programs to provide environmental information to consumers have been shown to be ineffective in changing behavior, and thus careful program design is essential [9].

A third approach is to discourage some types of individual or corporate consumption through taxes. Examples might include taxes on fossil fuels or taxes on use of hazardous materials in products. Taxation as an incentive structure has been studied extensively within economics; there is a literature on tax shifting for environmental purposes [10]. Additional approaches include the reuse of products, the recycling of products, efficiency improvements in industry, and a range of voluntary industry/government environmental programs (see *Take-Back Legislation and Its Impact on Closed-Loop Supply Chains; Remanufacturing; Recycling*). The OECD Environment Directorate reports that policy initiatives to promote more sustainable consumption patterns have been only mildly effective [11].

An approach to increasing the material and energy efficiency of manufacturing is industrial symbiosis. In Kalundborg, Denmark, a power plant, a petroleum refinery, a gypsum wallboard manufacturer, a pharmaceutical manufacturer, and the city's heating system all share resources. What would normally be waste products or waste energy is used as input feedstock in other facilities. A range of industrial symbiosis examples have developed worldwide [12].

MATERIAL AND ENERGY EFFICIENCY FROM A GLOBAL PERSPECTIVE

From a more global perspective, the underlying issue is the long-term relationship between technological development, social and economic development, and the environment. Global issues include not only geographically global environmental problems such as climate change and stratospheric ozone depletion but also overall

human health and welfare, the state of the economy, and resource availability. As indicated in Figs 1 and 2, energy use, as well as material use, has a dynamic relationship to economic development, determined not only by specific technological improvements (Table 1), but also by a broader set of economic, social, and policy developments.

Material budgets and cycles are a basic approach to evaluating large-scale environmental impacts and resource issues. A material budget assesses material flow into and out of a single reservoir; a material cycle assesses flows among several reservoirs. Important reservoirs include atmosphere, soil, mines, oceans, built infrastructure, landfills, human tissues, and food chains for humans and other species. The analysis involves not only quantifying use and disposal of materials, but also understanding the mechanisms that control the transport among reservoirs, the mechanisms that relate materials use to impacts, and the mechanisms through which materials use might change.

One aim of material cycle and budget research is to identify recycling opportunities and to understand how they might relate to resource and energy use minimization on a global basis. There have been a number of suggestions that materials could be mined from cities or landfills; the concentrations of metal resources in many waste streams are higher than for virgin resources mined from the earth [13]. Better understanding of the status, composition, and location of wastes, stockpiles, discards, and of the institutional and organizational requirements for access could open a wealth of opportunities for recycling and reclamation.

ENVIRONMENTAL IMPACTS OF CONSUMPTION

Material and energy use will change over time. Since the 1970s, a growing body of research has suggested that greater material efficiency, use of improved materials, and growth of the service economy are contributing to the "dematerialization" of the

economy. A related body of research suggests that expensive, scarce, or environmentally harmful resources may be able to be replaced by resources that are cheap, abundant, and environmentally benign. "Substitution" can be seen in the changes in energy sources that have occurred over the past century. As those sources have shifted from wood and coal to petroleum and natural gas, the average amount of carbon per unit energy produced has fallen, resulting in a "decarbonization" of world energy use [14].

There have been many attempts to alter consumption patterns to reduce environmental impacts. But there is no overall understanding of how far these efforts might go and whether there are fundamental limits or obstacles to the potential to change consumption patterns to reduce environmental impacts [15]. Beyond the short-term changes that might be induced by innovative policy approaches, there is a need for understanding the longer-term drivers of change in consumption patterns [16].

One approach to understanding the potential for changes in materials use is to analyze the metabolisms of cities. Cities are known to be strong attractors of resources and weak dispersers of them. Establishing the metabolic differences between cities in different parts of the world of different sizes, and in different stages of evolution could provide better understanding of the diversity in material use patterns.

There is need for better understanding of "rebound" effects, in which increases in production swamp the product-level environmental gains. Ultimately, the challenge is to understand the extent to which consumption can be decoupled from environmental impacts while raising the quality of life. Integration of economic and physical analyses could provide a comprehensive framework for understanding the relationship of environmental, economic, and technological change.

Resource constraints are complex and interdependent: one resource may be substituted for another, and resource availability depends on the technology of resource extraction [17]. There is a need for more rigorous understanding of the overall potential and

limitations of resource substitution, and of the potential and limitations for market forces and technology to overcome physical depletion of particular resources.

Claims and counterclaims about the need to constrain the consumption of materials and energy have characterized the most heated environmental policy debates. At one pole, it has been suggested that consumption of materials and energy in developed countries needs to be significantly reduced in order to protect and maintain environmental systems. At the other pole, it has been suggested that technological innovation will allow us to reduce environmental impacts without reducing economic growth or use of materials and energy. In some cases, technological innovation can surely obviate the need for constraints on consumption. In other cases, constraints on consumption (through, for example, energy taxes or restrictions on certain chemicals) can in themselves drive innovation. The development of a theoretical foundation for understanding the relative roles of technological innovation and consumption constraints in meeting environmental goals would provide a stronger basis for the long-term development of effective environmental policy [18]. At a broader level, the aim is to understand how the environmental impacts of industrialized systems, including energy and transportation, consumer products, cities, and food production, can be understood, managed, and reduced over the long term.

Negotiations are a particular form of communication and collective decision-making. Like all forms of collective action, negotiations involve different parties, which can be individuals, groups, or organizations. Three characteristics distinguish negotiations from other forms of collective decision-making as group decisions or social choice (voting) procedures:

- There is some conflict of interest between the parties involved.
- An agreement can be reached only by consent of all parties. If parties are not able to reach consensus, one particular outcome (usually the status quo) will take place.
- An agreement is not reached immediately but involves an interactive process in which offers are exchanged until a mutually acceptable solution is found.

Research on electronic systems to support negotiations began in the 1980s as an extension to the concept of decision support systems. Early research on negotiation support systems (NSS), for example, Ref. [1], focused on the multiperson aspect of negotiations and the possibilities of information technology to connect parties across time and space. The latter aspect gained importance with the rise of the internet and

the development of web-based NSS [2]. Nowadays, we can distinguish between communication-, decision-, and document-oriented approaches [3]. Surprisingly, e-mail is often used for business negotiations although it does not offer decision support or advanced communication support [4].

Connecting parties is only one function of NSS. As NSS were often seen as an extension to individual DSS, the potential of NSS to improve decision-making is an important concern. Lim and Benbasat [5] distinguished two main components in the architecture of an NSS, a decision support component and a communication support component, and postulated that these two components would have different impacts on negotiations.

The concept of decision support in negotiations draws attention to another important difference between individual and collective decision problems: in individual decision support, a support system assists a decision-maker to better achieve his or her objectives. Decision support in negotiations can have two different goals: supporting one party to better achieve its own goals vis-à-vis others or to support all parties to achieve higher level goals such as efficiency or fairness. In the latter case, the systems take the role of a neutral third party, and in the former case, they serve as advisors to one party. Modern negotiation theory, in particular negotiation analysis developed by Raiffa [6] and Sebenius [7], emphasizes the fact that these two goals are not necessarily in conflict and that finding win-win solutions that benefit all parties is important. However, most negotiations contain distributive elements in which the interests of parties are in conflict. Therefore, already early concepts of NSS [8] distinguished between support components for individual parties and decision support for a mediator. As negotiations by definition require consensus to reach an agreement, supporting parties to find a mutually acceptable solution, and breaking deadlocks in negotiations, is also an important goal of negotiation support at the collective level.

This decision support is also different from decision support for groups. Negotiations are more competitive than group decisions; support in group decisions aims at guiding group members to a consensus decision, which considers all (or a majority of) opinions present in the group. Thus, feedback and aggregation of preferences are a key concern. In negotiations, there are no “aggregated group preferences”; an agreement needs to satisfy individual interests to the extent that all parties can accept it.

Communication in negotiation follows a double goal [9]. On the one hand, the overall goal is mutual understanding. Without that, no interaction is possible. Thus, the negotiators aim to clarify their statements and to prepare a common ground for their interactions. On the other hand, the negotiators want to achieve their individual goals. To this end, they try to convince the partner to accept the current offer using information, threats, compliments, promises, and so on.

NSS are based on a prescriptive–descriptive perspective. Negotiators aim to make rational choices themselves, for which they need support. They also need to be aware of the fact that the other parties might not always act rationally but could be influenced by decision biases. Thus, game theoretic models that assume perfectly rational opponents are only of limited use for negotiation support. It should also be kept in mind that rational behavior in negotiations does not imply a focus on economic outcomes but has to consider that outcomes of negotiations involve several dimensions.

The process dimension is another characteristic of negotiations. NSS can intervene in different ways into these processes. Vetschera [10] distinguished three levels of process support: (i) *facilitation*, which does not guide the process into a particular direction; (ii) *interactive guidance*, which implements a specific interaction structure; and (iii) *normative guidance*, which provides solutions fulfilling normatively desirable criteria such as efficiency or fairness. Kersten and Lai [11] further differentiated NSS into (i) *passive systems*, (ii) *active facilitation–mediation systems*, and (iii) *proactive intervention–mediation systems*.

Passive systems only facilitate communication of geographically distributed negotiators and do not intervene into their behavior. Active facilitation–mediation systems provide advice (e.g., on offers a negotiator could make) only at the user’s request, whereas proactive systems monitor the process and interfere without explicit requests.

Support of negotiation processes serves different goals, individual goals of the parties, and collective goals characterizing the success of the entire negotiation. Collective goals can be of different nature. One obvious goal is to reach an agreement. If an agreement is reached, its quality can be evaluated on several dimensions. On the one hand, the agreement has to specify solutions for all issues of the negotiation, and these solutions can be evaluated in terms of efficiency and fairness. On the other hand, concluding an agreement is often not the end of the interaction between parties, the agreement has to be implemented via joint activities. The subjective evaluation and satisfaction of parties with the agreement, the behavior of their opponent(s), and the bargaining process have a considerable impact on their future relationship and their willingness to actually implement the agreement once they have left the bargaining table.

These different goals require different types of interventions. Reaching an agreement can be supported by improving the quality of communication between parties; thus, communication support (which can go far beyond providing communication channels) is an important topic in NSS. Methods from individual decision support can be applied and extended to enable negotiators to reach efficient and fair outcomes, whereas behavioral interventions can help parties to overcome deadlocks and improve their relationship in order to better cooperate in the implementation of an agreement.

COMMUNICATION SUPPORT IN NEGOTIATIONS

As mentioned earlier, the first perspective on negotiation support has been a decision-oriented one. However, communication is the

essence of negotiation. Without communication, no negotiation is possible as it is impossible not to communicate [12].

To understand an utterance, its contents and its mode need to be understood. According to the communication theories of Searle [13] and Habermas [14], the propositional content represents the factual level of an utterance, that is, what it is about. The illocutionary force represents the mode or the speaker's intention, that is, how it is to be interpreted, for example, as a promise, as a request, as a statement, or as an apology. Taken together, propositional content and illocutionary force provide the meaning of the utterance.

Understanding needs to take place on all levels of semiotics, that is, the syntactic, the semantic, and the pragmatic levels. On the syntactic level, the messages need to be transferred correctly; on the semantic level, their meaning must be unambiguous; and on the pragmatic level, the sender's intention must be explicit.

Tutzauer [15] argues that we can distinguish between offer communication and non-offer communication. The former consists of all the (mostly quantitative) details of the offers, whereas the latter complements offer communication and is equally important for negotiations. Non-offer communication has a factual function that aims at creating a mutual understanding about facts and positions. Furthermore, it has a procedural function to achieve mutual understanding about negotiation protocols, procedures, correlations between issues, and so on. Finally, its relational function focuses on achieving mutual understanding about the underlying norms, values, rules, and guidelines.

The duality of cooperation and competition is a distinctive characteristic of negotiation communication [9, 16]. Although understanding is a constant goal in negotiation, misunderstandings can be used strategically. To remain vague about a conflict issue can help to test out possibilities. Negotiation communication follows structured approaches that are efficient. However, there are also strategies such as time pressure that explicitly delay responses to the last moment in the hope of achieving better deals.

Finally, no negotiation will succeed without compromises and cooperation by all partners. However, negotiations can also be conducted in a situation where power is unevenly distributed, limiting the freedom of one party.

The medium in electronic negotiations has an effect on the communication processes. It can lead to a de-escalation of conflicts because of the asynchronous manner of interaction, thus generating more trust. As the utterances are made in writing, every utterance is documented and thus traceable, again leading to more trust.

Communication support of electronic negotiations is a complex topic. The Negoisst system [3, 17] is the only NSS offering sophisticated communication support. It is based on the theories of Searle and Habermas and implements a language-action approach [18]. On the syntactic level, a negotiation protocol guides the interaction. No deletion of messages is allowed so that every message is documented and traceable. On the semantic level, Negoisst employs a semistructured communication approach. Every part of the natural text message can be linked to a structured vocabulary so that the meaning (i.e., the semantics) of text is explicated and shared between the negotiators. On the pragmatic level, the mode of utterance (i.e., the illocutionary force) is made explicit using message types. Negotiators are thus supported in transparent and open exchanges that would lead to higher communication quality [9].

Compared to simple e-mail exchanges, such communication-oriented NSS approaches provide the benefit of combining structure and flexibility. The communication support allows for natural language messages and thus a high level of flexibility. At the same time, the controlled vocabulary, the messages types, and the interaction protocol provide the structure necessary to allow for traceability, explicit deductions of commitments, and easy search for (parts of) utterances.

DECISION SUPPORT IN NEGOTIATIONS

Decision-oriented tools in NSS focus on the economic dimension of negotiations and are

based on concepts from economics, decision analysis, and game theory. From an economic perspective, efficiency or *Pareto optimality* of the agreement is the main goal. An agreement is called *efficient* if no other possible agreement exists, in which at least one party would better off, and no party worse off. If two parties negotiate about one single issue (such as buyer and seller about price), then all possible outcomes are Pareto optimal, because one party can only gain if the other party makes a concession. In negotiations about multiple issues, possibilities for Pareto improvements do exist. If each party makes a concession in an issue that is of less importance to itself and obtains a concession in a more important issue, both parties can benefit. Decision support in negotiations is therefore closely linked to multiattribute decision-making.

Efficiency is not the only dimension along which outcomes of negotiations can be evaluated. Assuming that negotiators evaluate outcomes according to a given utility function, it is also possible to measure the fairness of outcomes via the (im)balance of utilities it provides to parties or by comparing it to normative solutions such as the Nash bargaining solution [19]. However, most existing NSS do not provide these calculations.

During a negotiation, offers and counteroffers are exchanged. After receiving an offer, a negotiator has to decide among three alternatives:

1. accept the offer;
2. reject the offer and terminate the negotiation;
3. reject the offer and make a counteroffer.

Decision support in negotiations thus should support negotiators in evaluating offers from the opponent, as well as candidates for own offers, and in the preparation of offers. Therefore, a multiattribute preference model is the basis of the decision support component of an NSS. Most of the widely used NSS such as Inspire [2], Negoisst [17], or SmartSettle [20] use an additive value function for this purpose, but there are also systems employing other preference models such as outranking relations [21].

For a comprehensive review of these different methods, see, for example, Refs 22 and 23. Most systems elicit a negotiator's preferences in a preparation phase before the actual negotiation and then employ the calibrated model to evaluate offers during the negotiation process.

For a negotiator, it is not only important to know the value of the most recent offer but also the history of the entire negotiation. An offer often implies a concession, and many negotiators tend to follow the principle of reciprocity and make concessions of a similar size as they received from the opponent. Therefore, they need to keep track of the opponent's as well as their own previous offers and concessions. Many NSS support this behavior by providing a graphical representation of the negotiation process, in which utility values of offers from both parties are plotted over time. Although the system has information about the utility functions of both parties, most systems only refer to a negotiator's own utility, because preferences are considered private information.

Economic theory and utility-based decision analysis usually assume that preferences are stable over time. This assumption is also required for the approach outlined earlier. However, several problems can arise in actual negotiations. Negotiators might change their preferences in view of arguments made by the other party. In this case, the utility function needs to be elicited again. Furthermore, offers might be incomplete and not specify values for all issues. Some systems (e.g., Negoisst [17]) therefore provide lower and upper bounds for utilities, which allow for the fact that issues not specified in the offer might take on their worst or best values. Finally, negotiators might be insecure about their preferences or reluctant to specify exact values. To overcome this problem, decision models under incomplete information can be incorporated in NSS [24].

Providing utility values of offers and counteroffers enables negotiators to solve the first decision problem outlined earlier: an offer made by the opponent should be accepted if it provides a higher utility than the counteroffer the negotiator is ready to make. Similarly, to decide about terminating

a negotiation, offers are compared to the disagreement outcome. However, calculating utility values provides only limited support for the preparation of a counteroffer. By reviewing the previous concession patterns, a negotiator might determine a target utility level for concessions. Some NSS [25] provide models to determine offers that lead to the desired utility levels. A more comprehensive approach [26] calculates a target utility level using desirable properties of the bargaining process such as concession making, reciprocity, and value creation. Multi-issue offers leading to this target utility level are selected based on their similarity to previous offers from the focal negotiator and the opponent. Given the complexity of these problems, the use of methods from artificial intelligence was also proposed for supporting mediators [27] and to advise individual negotiators via intelligent agents [25, 28].

Decision support methods in NSS deal with the exchange of offers as the substantive dimension of the negotiation process. However, they do not consider the relationship dimension of the negotiation process and the outcome dimensions related to it.

BEHAVIORAL SUPPORT IN NEGOTIATIONS

The interaction of negotiators also affects and determines their relationship to each other. Negotiations therefore can also be framed as a process of establishing, defining, or redefining the relationship between parties. A mere focus on the substantive dimension on negotiations would neglect the “human” (behavioral) dimension of these encounters.

Raiffa [6] has already pointed out the synergy of both, in what he called the art and science of negotiations. While decision analytic approaches constitute the science part, the art of negotiation comprises socioemotional skills, the knowledge about various bargaining and negotiation tactics, and how and when to employ them. This aspect is also closely related to the descriptive side of negotiation analysis.

There are two basic orientations toward conflict resolution. (i) Negotiators who have a *cooperative orientation* view negotiations as a process of joint problem solving. They

believe that a conflict can best be resolved when information about the problem and about one's own needs and motivations are shared. Furthermore, a cooperative orientation includes the willingness to understand the counterpart's motivations and needs and the effort to achieve the objectives of all parties. (ii) Negotiators having a *distributive orientation* view negotiations as a process in which one side wins and the other side loses. They attempt to achieve their own objectives at any cost and take everything that is possible from the negotiation table.

These orientations are reflected in a negotiator's strategy and tactics. The negotiation strategy determines the overall set of activities a negotiator implements, and tactics are the elements of this strategy. Integrative behaviors include information sharing, establishing a positive relationship and trust, concession making, and the like. Distributive behaviors include tactics such as making commitments, using power-related tactics, time pressure, and similar behaviors.

Empirical research has shown that negotiators with competitive orientation reach better own outcomes but at the same time reduce the prospects of reaching an agreement [29]. Integrative behavior such as cooperation and joint problem solving facilitates mutually beneficial solutions and helps the participants to “create joint value” [6] and to “invent options for mutual gain” [30]. However, individual outcomes tend to be lower [31]. It therefore depends on the situation, the conflict, and the dynamics of the process, which approach, strategies and tactics, is best suited to reach the negotiators' objectives.

Objectives are not always tangible and go beyond the substantive level. In some situations, the parties are forced to jointly resolve their conflicting interests. For example, in labor negotiations, law could impose deadlines for settlements. In such cases, a (well-) functioning relationship between the parties is an important outcome per se. However, even when parties have outside options, establishing a positive relationship during negotiations creates a solid basis to implement the agreement [32].

Trust is an important aspect of relationship building in negotiations. There is ample empirical evidence that a trusting relationship between negotiators has positive effects on negotiation processes and outcomes: mutual trust facilitates a problem-solving approach [33], the use of integrative strategies [30], and information sharing [34].

Behavioral negotiation support aims at providing negotiators with the knowledge when to use which strategy and how to build up a trusting relationship. However, providing behavioral advice is challenging, as ideas of “good” negotiation behaviors are disputed. Experienced negotiators have accumulated narrative knowledge, that is, “wisdom” about the art of negotiation, which is difficult to generalize and formalize. As there is no general criterion to guide behavioral support, the challenge is to provide guidance and orientation toward “good” agreements. Therefore, behavioral negotiation support has taken a process perspective and focuses primarily on increasing the prospects of an agreement [35]. Nowadays, only a few systems provide behavioral negotiation support. The first system, negotiator assistant (NA), was designed in the late 1990s as an electronic mediation support system to be used either by a human mediator or as an e-mediator in face-to-face negotiations [26]. Its successor, VienNA [36], was developed as a behavioral advice tool in e-negotiations [37]. Both systems are process focused and designed to direct the behavior of negotiators toward relationship and trust building, flexibility, and fairness [35]. The systems provide their users on request with diagnosis and analysis as well as appropriate advice.

The diagnosis function consists of a forced choice questionnaire to analyze the progress and actual status of the negotiation. The tool assesses how parties evaluate the status quo of the negotiation in five categories: parties, issues, activities, situations, and processes. Some questions prompt branching into new sets of questions. For instance, depicting the process as bargaining (win–lose) or problem-solving (win–win) approach leads to different questions addressing the tactics and strategies used. When all questions have been answered, the program generates

a diagnostic grid, which depicts “flexibility vectors” of the parties. This grid allows to forecast the expected outcome of the negotiation. The dimensions of the flexibility vector, which are reflected in the questions, stem from research on factors that influence negotiating behavior, whereas weights have been derived from effect size calculations in a meta-analysis of bargaining experiments. In addition, the model was cross-validated with nine historical negotiation cases (for more details, see Ref. 38).

The analysis and advice functions search for the sources of impasses and stalemates and provide tailor-made recommendations for each user. The system utilizes an expert database on negotiations and identifies areas of difficulties using the information supplied in the diagnosis phase. The most problematic areas are presented to each user individually. For instance, the system might identify that negotiators follow a win–lose bargaining approach and are not flexible enough to trade-off issues. In this case, the system would suggest a logrolling strategy, in which negotiators trade-off less important for more important issues.

OUTLOOK AND CONCLUSIONS

The different approaches to negotiation support outlined earlier have reached different levels of maturity. Nevertheless, potential for future developments exists in all of them. Decision support is probably the approach with the longest research tradition. Still, several issues remain open in this field, in particular the development of more active support methods to suggest offers. Analytical decision support in its present form operates from a strictly prescriptive perspective, providing users a “correct” solution. Another challenge could be to tailor support strategies more specifically to a user’s individual needs to counteract specific decision biases a user might have (or, in a one-sided approach, to exploit biases of the opponent).

Communication support is more difficult to realize as it deals with nonquantifiable aspects of negotiation. One challenge is to realize a proactive communication support, actively supporting the user in his or her

choice of communicative strategies, in preventing misunderstandings, and communication conflicts.

Behavioral support is a more recent concept, which offers many opportunities for research. One particular aspect of negotiations that so far has been rarely addressed in this context is the role of emotions. Emotions are at the core of conflict interactions, they might hinder negotiators to behave rationally [39]. Emotions emerge from the individual's evaluation of events, are either positive or negative, and predispose individuals to bivalent behavior, that is, either approach or withdrawal [40]. Because of emotional reciprocity and contagion, the expression of emotions leads to a nonconscious and automatic mimicking of counterparts. Emotional stimuli may cause distinct reactions by individuals and create complex patterns in human interactions [41]. Empirical research in negotiations shows that negative emotions increase competitiveness, whereas positive emotions increase cooperation [42]. However, negative affect can also be positive in negotiations: expressions of pain or distress may induce cooperative behavior, and anger and fear may motivate to overcome a crisis [43]. Similarly, positive emotion may negatively affect negotiations by causing biased judgments or expectations. The analysis and management of emotions in negotiation processes has not yet found appropriate consideration in behavioral decision support. It would be necessary to monitor negotiation processes to identify problematic emotional patterns in order to intervene into the process in due time.

The three forms of support we have described earlier address different aspects of the negotiation process. However, their integration and consistency across dimensions is an important issue, which is not yet addressed in existing NSS. Existing systems typically do not provide support in all three dimensions. Integrated support could not only help negotiators to overcome a wider range of obstacles but also address the question of consistency across dimensions. Consistent behavior (e.g., open and cooperative communication about preferences and large concessions) will transmit a coherent

message to the other party and thus could improve the possibility of success. However, inconsistencies could also be used as a deliberate negotiation device. Identifying such (in-) consistencies, both by the supported negotiator and by the opponent, and providing advice how to deal with them, could be an important function of future integrated NSS.

INTRODUCTION

The overall process of arriving at an informed decision usually includes the likelihood of events or the distribution of unknown quantities. Numerous important analyses have relied on expert judgment. North and Stengel [1] used expert judgments to assist the US magnetic fusion energy program in determining the best fusion concepts to fund. Keeney *et al.* [2] examined setting standards for ambient air quality, using expert judgments to develop a risk-assessment model that related adverse health effects to alternative carbon monoxide standards. Winkler and Poses [3] performed assessments with physicians to provide judgments of patient survivability in critical care situations. DeWispelare *et al.* [4] studied the performances of high level nuclear waste geologic repositories over a 10,000-year period with experts assessing changes in the climate over this period. Expert judgments have been used in numerous risk assessment situations [5,6], including numerous maritime risk assessments [7–11].

The use of expert judgment is not without its difficulties. Human beings tend to incorporate conscious and unconscious biases in their predictions of uncertainties. We use “primitive cognitive techniques” to simplify the task of assessing uncertainty, called *heuristics*. Heuristics are easy to use and simplify the task, but result in systematic faults with the resulting judgments, called *biases*. This article focuses on ways to improve the assessments provided. When an expert is asked to

provide a probability of an event’s occurrence, they search their memory for applicable knowledge, combine that knowledge with the information at hand, and attempt to provide the best feasible judgment [12]. Therefore, the judgment provided will depend on what is retrieved from the subject’s memory, what current information is used, and even the order in which the subject thinks about these pieces. Gigerenzer *et al.* [13] point to the literature, suggesting that memory is often “excellent in storing frequency information from various environments and the registering of event occurrences for frequency judgments is a fairly automatic cognitive process requiring very little attention or conscious effort.” This series of cognitive processes that occur without effort in the subject leave much room for error of interpretation of uncertainty and that error can be presented as a biased assessment [14].

The representative heuristic is used when assessing a probability that an object belongs to a specific category. When using representativeness, we evaluate the probability “by the degree to which *A* is representative of *B*, that is, the degree to which *A* resembles *B*” [15]. This heuristic involves making the judgment by comparing the information provided on the subject with a stereotypical member of the category. The more complete the resemblance between the two, the higher is the probability that the subject will be placed into the category. There are several biases that result from the representative heuristic. Kahneman and Tversky [16] describe a representativeness study where students are asked to predict the career area for a fictitious character called Tom W. “Tom W. is of high intelligence, although lacking in true creativity. Tom has a need for order and clarity, and for neat and tidy systems in which every detail finds its appropriate place. His writing is rather dull and mechanical, occasionally enlivened by somewhat corny puns and by Hashes of imagination of the sci-fi type. He has a strong drive for competence. He seems to have little feel and

little sympathy for other people and does not enjoy interacting with others. Self-centered, he nonetheless has a deep moral sense” [16]. One group of students is asked to predict the proportion of the US population that is employed in each of nine career areas (business administration, computer science, engineering, etc.) to form a base rate. Another group is asked to assess the similarity of Tom W. to people employed in each of these areas by ranking from the most to least similar. A third group is asked to assess the probability that Tom W. is employed in each of these areas. The correlation between the assessed probabilities and the similarity rankings was 0.97, while the correlation between the assessed probabilities and the base rates was -0.65 . Thus, the probability assessments were primarily based on the representativeness of the description for each career area and completely unrelated to the overall base rates of each career in the population.

The availability heuristic can be used when a probability of an event’s occurrence is assessed on the basis of the ease with which one can retrieve similar events from memory [17]. It is often easier to recall instances of large classes than those of less frequent classes. External events and influences can have a substantial impact on the availability of similar incidents, such as the media or particularly emotional events [18]. Kahneman *et al.* [19] suggest that witnessing an accident will have a greater effect on a person’s judgment of the probability of an accident than reading about it in a newspaper. Tversky and Kahneman [17] describe an experiment where subjects were read lists of names of famous men and women and were asked to assess whether there were more men or women on the list. Some subjects were given lists where the men were more famous and they tended to respond that there were more men on the list. Some subjects were given lists where the women were more famous and they tended to respond that there were more women on the list. Thus, the ease of recall affected the judgment. This is also true, for instance, in searching memory and imagining possible events.

An individual will often assess a probability by selecting an initial anchor point

(suggested either by the formulation of the problem or by result of partial computation) and then adjusting the anchor based on his/her knowledge of the specific event [20]. Tversky and Kahneman [15] term this heuristic anchoring and adjusting. The adjustments are usually inadequate since different estimates are obtained when based on different anchors. For instance, if we ask to provide a best estimate of an unknown quantity, such as the median, and then ask for a range, such as the 25th and 75th percentiles, then it is likely that the range will be too small. This bias is called *overconfidence*, as it appears that we are overconfident in our estimates. The best estimate is anchoring our range estimates and we do not adjust sufficiently away from it.

Given the tendency to use such heuristics, we must design both the elicitation question and the elicitation process to assist the experts in providing their best possible assessment. We must also ensure that we are asking for assessments that are sufficiently specific and within the range of the expertise of those asked, a task best achieved with correct decomposition of the problem. In the section titled “What is a Good Probability Judgment?” we discuss the desirable properties of a probability judgment. Elicitation processes are discussed in the section titled “Elicitation Processes for Minimizing Biases.” Decomposition is discussed in the section titled “Elicitation Methods for Minimizing Biases.” In the section titled “Conclusions,” we discuss elicitation methods.

WHAT IS A GOOD PROBABILITY JUDGMENT?

A major question in using probability judgments in decision analysis is the validity of the judgments. In psychometric terms, validity is the relationship of probability judgments to an independent and previously validated scale [12]. Calibration is often used as a measure of validity. A judgment is well calibrated if the events that the expert assigns a probability p to occur $p\%$ of the time. For example, a forecast of a 60% chance of precipitation is well calibrated if precipitation is observed on 60% of the days when

that forecast is made. From a statistical perspective, p must be close to the observed relative frequency of the event, $\hat{p}$. Wallsten and Budescu [12] observe that calibration is not a measure of validity in the strict psychometric sense as p and $\hat{p}$ are not necessarily independent, as they are both based on available data. Keren [21] notes that p is in fact a measure of the expert's belief and therefore does not need to correspond to $\hat{p}$ to be valid, particularly if the expert has not observed the same data as used to estimate $\hat{p}$.

The concept of calibration is related to the overconfidence bias [22]. Specific overconfidence occurs when $p > \hat{p}$ for a given event. General overconfidence occurs when $p > \hat{p}$ for $p > 0.5$ (for Bernoulli events). Most literature refers to general overconfidence, leading to the well-known S-shaped calibration curve and probability judgments that are more extreme than the corresponding relative frequency. Keren [21] also suggests that if the errors in representing the expert's true beliefs are random, then an S-shaped curve can at least partly be explained by regression to the mean (see also Refs 23 and 24). Juslin [25] suggests that the phenomenon could be due to the experimenter's choice of almanac questions, a phenomenon borne out by Murphy and Winkler [26], who find that weather forecasters are well calibrated within their domain expertise. However, Lin and Bier [27] find that most overconfidence is random and not due to the question asked.

Calibration is not sufficient for a good probability judgment. Consider the case of an expert assessing the probability of the sex of a newborn baby. An expert can say 50–50 and be perfectly calibrated as this is the observed relative frequency across all births, but this does not provide any helpful information to the parent (decision maker) [22]. Alternatively, an expert could always get the sex wrong, but with absolute certainty. This expert is perfectly miscalibrated, but useful if you know about the systematic bias and can correct for it. Essentially, an expert that is diagnostic (p is related to $\hat{p}$ in some known way) is all that is truly needed.

Another problem with probability judgments occurs when multiple probability judgments are requested, but the set of judgments are incoherent (do not obey the laws of probability). An example of this is the conjunction fallacy that is caused by the representativeness heuristic. Tversky and Kahneman [28] offered subjects a description of a woman called *Linda* that was representative of a feminist and asked them to rank the following statement:

1. Linda is an active in the feminist movement.
2. Linda is a bank teller.
3. Linda is a bank teller and is active in the feminist movement.

Many subjects ranked the third option above the second, even though this violates the rules of probability.

The calibration, resolution, and coherence of probability judgments can be improved by the way the analyst interacts with the judge or by the analysis of the judgment. Essentially, we can improve the judge or we can improve the judgment. In this article, we concentrate on improving the judgment through the elicitation process, the decomposition of the problem, and the specific elicitation question or method. In the section titled “Conclusions,” we point the reader to other articles on improving the judgment.

ELICITATION PROCESSES FOR MINIMIZING BIASES

The analyst should aim to structure a situation where biases are minimized and the assessments determined actually symbolize the subject's opinions [12]. This section overviews processes presented by Spetzler and Von Holstein [29] and Keeney and Von Winterfeldt [30] that are aimed at eliciting accurate probabilities while minimizing the effects of the biases presented in the previous section.

Spetzler and Von Holstein [29] start with a set of five principles to use as a guideline for encoding uncertain quantities, and violating any one of these principles can lead to

problems in the encoding process. Only those uncertainties that are important to the decision itself are chosen. The quantity is defined as an unambiguous state variable (a state variable being one that has values beyond the control of the decision maker). The quantity is structured carefully with thoughtful consideration to conditionalities. The quantity is defined precisely by performing the clairvoyance test. The quantity is described using an appropriate scale that the subject finds meaningful, so that the subject does not spend time trying to fit his/her answers to the scale versus evaluating the uncertainty. These principles ensure the clarity of the task required of the expert and reduce the cognitive effort by using familiar language, definitions, and scales.

Spetzler and Von Holstein [29] provide an interview process procedure that is divided into five phases. Their process is for eliciting probabilities from a single individual:

1. *Motivating* introduces the subject to the encoding task and explore the possibility of any motivational biases;
2. *Structuring* defines the uncertain quantity to be assessed.
3. *Conditioning* reviews how the subject assesses probabilities so that any potential biases can be avoided.
4. *Encoding* encodes the uncertain quantity.
5. *Verifying* reviews the assessment and tests for subject approval.

Wallsten and Budescu [12] suggest that when encoding an expert's (or nonexpert) opinion, it is imperative that the analyst carefully specifies the class of events in question, the sources of information to be considered, and the potential causes of unreliability in the information (e.g., sampling error). The anchoring and adjusting heuristic can play a key role when/if the analyst accidentally gives undue weight to the earliest information considered. The analyst should review the heuristics with the subject to introduce them to how most of the people process uncertainty and thus attempt to eliminate most of the biases associated with the heuristics.

The suggested route to encode the quantities is to begin by asking for the extreme values before moving to central estimates. This route is suggested to ensure that the biases associated with anchoring and adjusting are eliminated. In the verifying phase, if the subject is not comfortable with the assignments provided, the process may need to be repeated until the subject is confident with his judgments. A typical interview should last 30–90 min, depending on the complexity of the situation. Spetzler and Von Holstein [29] make a final note that the preencoding steps generally take longer than the encoding steps but are the most essential to good probability assignments. In addition, interactive techniques have proven to facilitate judgment by minimizing randomness and eliminate unwanted inconsistencies [12].

Keeney and Von Winterfeldt [30] provide lessons learned from the NUREG 1150 study and a recommended process for eliciting probabilities from experts. The recommended process for eliciting probabilities from multiple experts consists of seven components:

1. *Identification and selection of the issues* emphasizes that, even before the study begins, it is important to recognize all uncertainties that need expert probability elicitation and select the ones that need to go through a formal elicitation procedure.
2. *Identification and selection of the experts* should involve both specialists and analysts. Specialists should be the most knowledgeable in their field of study and the analysts who perform the elicitation should have expertise in probability theory, statistics, and decision analysis.
3. *Discussion and refinement of the issues* is to ensure that the specialists understand the project and what is expected of them and arrive at unambiguous definitions of the events and the uncertainties that will be elicited.
4. *Training for elicitation* is performed by an analyst with an intent to familiarize the specialist with the techniques used in elicitation, provide them with

an assessment practice session, inform them of the potential biases that can occur, and motivate them on their judgment task.

5. *Elicitation* is an interview between the specialist and analyst with a possible generalist assistant who provides project inputs and recording services.
6. *Analysis, aggregation, and resolution of disagreements* is not always feasible to combine the specialist's judgments during the elicitation process, thus the analyses should be provided to the specialist as soon as possible after the interview so that any necessary changes can be made while the interview is still fresh in mind.
7. *Documentation and communication* is performed throughout the entire elicitation procedure. At the very minimum, documentation of elicitation results and reasoning, event definitions, expert identification and selection, the training session, the actual elicitation session, and the aggregation and analysis should be maintained.

The first two components of this process are self-evident, deciding what should be assessed and by whom. The third component, refinement of the issues, should be conducted in a meeting of the specialists and analysts. The in-depth discussion of definitions amongst experts should help eliminate biases associated with the representative heuristic with the elimination of any ambiguity.

After the first meeting is completed, the issues clarified, and the specialists given time to think about the issues at hand, the training for elicitation should be conducted. Wallsten and Budescu [12] determined that the accuracy of the assessments determined by either direct or indirect methods could be increased with just simple and short training procedures. Benson and Onkal [31] demonstrate that training can reduce biases in judgments. Keeney and Von Winterfeldt [30] suggest that the elicitation itself should start with an informal discussion of the specialist's approach to the issue and review of the event definitions in order to

map out the decomposition to identify the necessary judgments. Next, a series of easy questions should be asked to determine the probabilities or probability distributions of the decomposition, followed by harder questions. Consistency checks should be administered once the judged probabilities are obtained. The end points or boundaries should be defined, followed by the fractiles. The determination of end points first helps eliminate any anchoring that might occur on behalf of the specialist. The median judgment should be the first fractile assessed. A graphical depiction should be maintained throughout the process to provide continuous consistency checks and feedback to the experts. Murphy and Winkler [26] show good calibration among weather forecasters who receive continuous feedback on the accuracy of their forecasts, implying that such long-term training can also be beneficial. In experimental testing, González-Vallejo and Bonham [32] demonstrate that providing both positive and negative feedback improves calibration.

The next step in this process is the analysis, aggregation, and resolution of disagreement components. The analyst aggregates across the experts by an averaging process and performs sensitivity analysis. A final group meeting can be held for all specialists and analysts involved to establish any agreements or disagreements on the probabilities elicited or events in question.

Mellers and Locke [33] have additional suggestions for the elicitation procedures to eliminate biases. The first concerns disclosure, a common procedure for constraining self-interest. This suggestion is based on the assumption that when a subject reveals a conflict of interest he or she will provide a less biased assessment. If not, the analyst can discount the assessment to achieve an unbiased decision. Another study, however, suggests that disclosure actually increases the subject's bias, and also increases the analyst's discount, although not enough to correct the initial increase in bias. Mellers and Locke [33] believe that the subjects may feel their self-interests are disclosed and so the decision makers should rely more heavily on their own information without knowing how

much the conflict of interest has affected the provided assessment. In real life, if the decision maker trusts the subject providing the assessment and the decision maker is unsure of his own information, having a provided disclosure may allow the interpretation that the subject's information is more credible.

Another suggestion from Mellers and Locke [33] for the elimination of biases during the elicitation procedure is to apply accountability to the situation, because predecision accountability to an unknown audience can reduce cognitive biases, especially those biases that result from lack of effort of understating one's own judgmental processes. This suggestion can however have a null or detrimental effect if the decision maker hedges his choice by sticking with the status quo. For the last suggestion, Mellers and Locke [33] state that some tasks, such as recall of items and the effects of anchoring and adjusting, showed improved performance with the use of incentives. Incentives can however be harmful if the task is too complicated, and most studies actually showed little effect on performance with the use of incentives.

The elicitation process is just as important as the method used. The process must ensure that all experts are using the same definitions of the events or quantities in question and that the experts understand the biases that can be introduced if they use simple heuristic strategies. Feedback and the chance for revision of initial assessments are also a critical part of any elicitation process.

DECOMPOSITION FOR MINIMIZING BIASES

Moskowitz and Sarin [34] study the assessment of conditional probabilities. They present difficulties associated with causal versus diagnostic relationships between events, as well as positive versus negative relationships. In assessing $p(B|A)$, the relationship is causal if A is perceived as the cause of B and diagnostic if B is perceived as the cause of A . The study found that probability judgments tend to be higher if the relationship is perceived to be causal. This is because individuals perceive a

causal relation as being more informative or representative. In addition, the relationship is positive if the occurrence of A increases the probability of B occurring and negative if it reduces the probability of B occurring. The subjects felt that a positive relation was more informative, so higher probabilities were assessed. Normatively speaking, however, neither the causality/diagnostic relationship nor the positive/negative relationship should influence the conditional probability assignments. These effects are noted in the study reviewed below.

The study involved undergraduate students enrolled in managerial statistics with knowledge of the concept of probability. The subjects assumed the role of a bank lending officer assessing the base rate probabilities of delinquency (D) and good (G) or bad (B) credit. The subjects assessed the conditional probabilities $p(D|B)$, $p(B|D)$, and $p(D|G)$. The subjects first specified their perceptions of the relationship strengths between delinquency and credit rating. They then assessed conditional probabilities for 15 questions partitioned into five groupings and provided their assessments. The subjects were given a joint probability table with the marginal event probabilities included as an assessment aid. They could then reassess several of the previous questions, and finally rate the probability table as an assessment aid on a scale with descriptions as to how it helped.

Each groups questions were designed to test the consistency with respect to the probability axioms that must be satisfied for a conditional probability, say $p(B|A)$: $p(B|A) \leq 1$, $p(B|A) \leq \frac{p(B)}{p(A)}$, $p(B|A) \geq \frac{p(B)+p(A)-1}{p(A)}$, and $p(B|A) \geq 0$. A number of violations were observed. The authors suggested that the subjects ignored the based rate frequency of the events (the base rate bias) and the causal versus diagnostic and positive versus negative relationships. Causal and positive relationships led to more revisions and higher conditional assessments than diagnostic and negative relationships. With the addition of the probability table, the subjects tended to have more confidence in the marginal probability assessments and were more likely to

revise their conditional probability assessments. The results suggested that the use of a probability table drastically improves the consistency, reduces the frequency of the violations of the conditions, and lessens the effects of the causality/diagnostic and positive/negative relationships. However, if the probability table is not used properly, the conditional probabilities can be inconsistent.

Decomposition is the process of breaking down a probability assessment into smaller or manageable chunks. Clemen and Reilly [20] recognize three scenarios where decomposition is appropriate: thinking about how the event in question is related to other events, thinking about what uncertain outcomes could lead to the occurrence of the event in question, and thinking about what uncertain outcomes must happen for the event in question to occur. Further, the best decomposition to use is the one that is easiest to contemplate and that gives the most transparent view of the uncertainty in question. Ravinder *et al.* [35] sought to reduce inconsistency by relying on decomposition rather than direct elicitation. They assessed the impact of the decomposition procedure on the reliability of the assessed probabilities.

Ravinder *et al.* [35] regard decomposition as a useful technique for reducing the complexity of challenging judgment problems. The decomposition approach is able to capture the relationship between the event in question, the target event, and its background events. For example, the survivability of a patient may depend on the disease, the strength of the patient, the complexity of the medical procedure performed, and so on. The distribution of the survivability of the patients could be assessed conditionally on the outcome of the disease they had or even conditioned on multiple events, like the disease the patient had was nonsignificant, the complexity of the surgery was minuscule, and the patient's strength was favorable. The decomposed judgments are later combined using the law of total probability. We denote the probability of the target event as A and assume that it is assessed conditionally upon its background events $B_1, \dots, B_n$. The event B_i can be a single event or a

scenario and the set must form a mutually exclusive and exhaustive partition of the relevant event space ($\sum_{i=1}^n \Pr(B_i) = 1$). The probability of the target event is $\Pr(A) = \sum_{i=1}^n \Pr(A | B_i) \Pr(B_i)$. Evidently, elicitation by decomposition involves more questions than direct assessment as marginal and conditional probabilities must be assessed for each background event.

Ravinder *et al.* [35] draw several conclusions to minimize inconsistency in conditional probability assessments as follows:

- Decomposition can reduce random errors associated with probability encodings.
- Error reduction has an upward limit and assessing additional probabilities will not be necessary to obtain further reduction.
- The marginal probabilities of the conditioning events should be selected to be equal.
- Conditional probabilities that cover an extremely wide range of values should be avoided.
- The component probability assessment errors should be as small as possible and the analyst should try to maintain independence of the component assessments.
- A decomposition approach is conceptually simple, is implemented easily, and apparently has great potential for error reduction.

Andradóttir and Bier [36] also address the trade-off between simplifying judgment tasks by decomposition and adding additional estimates with ensuing cumulative error. They find that large numbers of conditioning events are not necessary, but it is better to edge on the side of too many and not too few to avoid significant drop-offs in performance. It is also important to ensure that the marginal probabilities of conditioning events can be accurately estimated.

Howard [37] notes that information is generally received fragmentally when it comes from an expert or a group of experts, and the daunting task of gathering and coordinating

these fragments can be lessened with the use of knowledge maps. A knowledge map is centered on the concept of influence diagrams and captures the relevant knowledge of an event. An influence diagram represents the actions that a decision maker may take and the information possessed at the time of the decision by way of decision nodes (boxes representing an action to be taken), chance nodes (circles representing an uncertain event), and arrows (showing connectivity between the events). A knowledge map is also a method for decomposing a complex, uncertain event into workable and more easily understood units.

Howard [37] uses the [17] study of Tom W. to demonstrate how knowledge maps can aid in correcting the representative heuristic. This study presents a high school description of Tom as introverted, mechanically minded, lacking in creativity, and well organized to a group of students who are supposed to assess the likelihood that Tom would be enrolled in a specific field of graduate study. Generally, the assessors relate Tom to being a “nerd” and subsequently place him into the field of computer science or engineering without regard to the relative enrollment populations of each field of study. Howard [37] first suggests decomposing this problem. One could assess the likelihood that a student would study each field and the likelihood of a report such as Tom’s given he is in each field of study. Next, the assessors can multiply the two likelihoods and normalize to yield a posterior probability that Tom works in each field.

This first step improves understanding but does not capture everything relevant to the second probability, that a report like Tom’s would describe someone in a given field. Howard believes that additional relevant information can be captured with three considerations:

- Is Tom’s personality now different from that in high school (when the report was completed)?
- Are there valid issues with the report itself?
- Is personality a good indicator of field of study?

Figure 1 shows the corresponding knowledge map capturing these considerations.

Despite the fact that this knowledge map encompasses all the necessary information for determining the likelihood, it does not reflect the notion that an individual might not feel comfortable trying to assess the relevance of the present personality to graduate field because they do not think about characterizing the personalities of graduate students. Yet, assessing the probability distribution on field of study and what is known about the personalities of graduate students in each field is probably more comfortable for most assessors. The redundancy map in Fig. 2 represents this way of thinking. The assessments for the original knowledge map (Fig. 1) can now be determined by using the new assessments from Fig. 2 iteratively until the personality now distributions agree and then performing the Bayesian reversal of the arrow from “graduate field” to “personality now.”

“A knowledge map represents a possible assessment order for the joint distribution on the uncertain quantities (events) it contains.” In some instances, the decision maker is only interested in the joint distribution of a few events [37]. For these instances, constructing a disjoint knowledge map can simplify the assessment. The corresponding example provided by Howard [37] is assessing a probability distribution on the income of the next person to enter the room. To aid in thinking about this particular assessment, the subject might consider the amount of education and the age of the individual. With these additional events comes additional assessments and the subject is only interested in the distribution on income. Thus, the subject would want to draw the corresponding disjoint knowledge map represented in Fig. 3. The subject can now assess a distribution on age and another on education given age. The law of total probability can then provide a distribution for education. As Howard suggests, creating disjoint knowledge maps can reduce the difficult task of assessment to manageable pieces. One problem with disjoint knowledge maps, however, is that they only represent one point in the spectrum and they do

Figure 1. A basic knowledge map for Tom W.

Figure 2. A redundant knowledge map for Tom W.

Figure 3. A redundant knowledge map for assessing income.

not provide all the consistency checks and inferences of a complete knowledge map. Yet, overall, knowledge maps allow indirect assessment and the use of redundant and disjoint knowledge maps “can often reconcile the needs of consistency and convenience” [37].

The literature reveals that the events and quantities in question must be suitably

decomposed before elicitation. Conditionalities must also be fully understood by the experts during elicitation. Decomposition can improve probability judgments, but can also introduce inconsistencies. However, these inconsistencies can be reduced. If event A causes event B , then we should elicit $p(B | A)$ rather than $p(A | B)$. Further, if $p(B | A) < p(B)$, then we can elicit $p(\text{not } B | A)$ to ensure a positive relationship. Knowledge maps can also help reduce inconsistencies. Using knowledge maps, a few conditional relationships are elicited at a time and then the expert is informed of inconsistencies and asked to iterate their assessments until coherent conditional probabilities are obtained.

ELICITATION METHODS FOR MINIMIZING BIASES

Spetzler and Von Holstein [29] review methods for eliciting probabilities. Questions

can be answered either directly (by providing numbers) or indirectly (by choosing between alternatives until an indifference point is determined). Direct assessment, or structured questioning, supports data generation with questioning schemes that are designed to trigger elements in the subject's associative memory [38]. There are multiple indirect response techniques to choose from such as odds-based lotteries and reference lotteries. Verbal encoding is the most common direct method studied in the literature, where verbal descriptions are used to characterize events and then quantitative interpretations are added. Benson *et al.* [38] suggest that graphical representation is one of the most used and best-developed aids for assessment, with decision trees being the dominant form of problem representation. However, graphic representation, like other existing aids, has a limiting account of relevance and therefore has a tendency to constrain rather than exploit the variety of reasoning strategies that humans are capable of [38]. The indirect response mode is generally superior to begin encoding, because subjects tend to have trouble in giving direct numerical probability [29]. Additionally, indirect assessment avoids the availability heuristic because subjects do not assess probabilities directly based on memory. We highlight two indirect methods, an odds-based lottery (or betting) technique and a reference lottery (or probability wheel) technique, and one direct method, verbal encoding.

Using the lottery technique, we consider bets for and against the occurrence of an event. The expert is given odds $X : Y$, which means that they lose Y if the event does not occur and win X if it does. The expert is asked if he/she would take those odds on the event occurring or if they would prefer those odds for the event not occurring. If they prefer to bet on the event occurring then $p(\text{Event}) > \frac{Y}{X+Y}$. If they prefer to bet on the event not occurring then $p(\text{Event}) < \frac{Y}{X+Y}$. The elicitor must start with two bets that bound the probability and then reduce the bounds to arrive at a final point of indifference. At indifference, $p(\text{Event}) = \frac{Y}{X+Y}$. This bounding approach avoids the anchoring heuristic if the initial high and low values are extreme

enough to bound the probability. The expert could still employ either the representativeness heuristic or the availability heuristic depending on the description of the event that is considered. However, the motivation of betting is used to engender additional effort in the thought process used to determine the expert's answer. This can avoid the use of simple thought processes.

Spetzler and Von Holstein [29] call the odds-based lottery a value method because the payoffs are varied and the probabilities are kept constant. The odds-based lottery technique works well with experts who are familiar with betting and for events that they are willing to place bets for. Weather forecasters familiar with betting might be willing to place bets on whether it will rain tomorrow, but oil tanker captains would probably not be willing to bet on a large oil spill occurring in the next year. The technique also assumes that the expert is risk neutral over the range of bets considered [39]. If the odds considered are too large, particularly on the loss side, then the expert's risk preferences can bias the results.

A reference lottery asks an expert whether he/she would like to bet on the event occurring or on another lottery with known probability (the reference lottery). A probability wheel is commonly used as the reference lottery to help the expert visualize the probability. However, red and blue balls drawn from a bag (or urn) and drawing cards from a deck are other examples that may work depending on the expert's familiarity with the specific visualization. The prizes for the event lottery and the reference lottery are fixed, so the same prize is awarded if the expert "wins" or "loses" either lottery. The expert must prefer the prize awarded on a "win." A high probability and a low probability reference lottery are offered first to create upper and lower bounds on the probability of the event, like with the betting approach, and then the bounds are narrowed until the expert reaches indifference between the event lottery and the reference lottery. At indifference, the probability of the event is equal to the probability of a "win" on the reference lottery. The prizes are fixed, so the expert's risk preferences do not bias the

results and framing effects are avoided. However, the technique is still based on betting, so the betting on the event must not be distasteful to the expert. Spetzler and Von Holstein [29] call the reference lottery a probability method because the probabilities of the reference lottery are varied and the payoffs are kept constant.

Fractile or quantile methods are also important when the distribution of an unknown quantity X is needed, not just a simple probability. However, we can elicit fractiles, $p(X \leq x)$, using either the betting or reference lottery method and specifying the event to be $X \leq x$. Fractiles can then be assessed for multiple values of x and the assessed cumulative distribution function plotted to provide feedback to the expert. Abbas *et al.* [40] empirically evaluate fixed probability methods to the fixed value methods for eliciting quantiles. They find a slight but consistent improvement in accuracy and precision with fixed-value methods. The subjects also responded faster and found the questions easier with fixed-value methods.

Verbal assessment uses descriptive words such as most likely, fairly, least likely, and so on. Wallsten *et al.* [41] observe that people prefer to communicate verbally and receive information numerically. In addition, Wallsten *et al.* determined that the overall quality of decisions made from verbal probability assessment is not different from those made with numerical probability assessment. The main difference between the two assessment methods is that, while overconfidence was prevalent in both models, the magnitude was greater in the verbal response method. This is partially due to the use of the 0.5 probability response with the numerical method as a hedge, whereas judges tended not to use the tossup (equally likely) response with the verbal method. Thus, the verbal method may lead to greater honesty. The authors suggest that the analyst provide a fixed list of approximately 11–15 chance-words when using the verbal method. The subject should then assign probability values for the words. The main advantage of verbal encoding is that the forecaster is more comfortable with their assessments. The verbal method relieves

the stress of defending the assessment because it allows vagueness. However, numerical encoding provides a higher level of resolution.

In summary, the literature shows that direct verbal assessment is as good as direct numerical assessment and is easier for the experts. However, indirect methods, particularly the reference lottery method, can motivate experts to think beyond the simple heuristic-based probability assessments.

CONCLUSIONS

In this article, we have discussed how problem decomposition and appropriate elicitation methods and processes can be used to improve probability judgments. We have discussed several approaches. First, we must choose the right events for which to request probability judgments. The analyst must ensure the clarity of what is being asked, decompose events to a reasonable level, and ensure that conditionalities are well understood. This helps to reduce biases caused by the representativeness heuristic. Second, the analyst must choose the right elicitation method to provide motivation to put forth sufficient effort and provide good judgments. It is also crucial to avoid framing effects and offering anchors. While effort must be maximized, it is also important to reduce the cognitive effort required to form a good probability judgment. This allows the mental effort to be spent on retrieving appropriate facts from memory and thoroughly considering their impact on the judgment. Third, incentives can increase motivation, such as scoring rules (see **Scoring Rules**). Last, training and feedback on performance (in terms of calibration, coherence, and resolution) have been shown to reduce biases that can be caused by the availability heuristic.

These methods can help reduce potential biases caused by simple, heuristic thought processes. However, we should point out that the title of this article uses the phrase “minimizing biases,” not removing them. Morgan and Henrion [42] and Benson and Onkal [31] conclude that biases can be reduced, but not removed. There are also numerous

methods for improving probability judgments during the aggregation process. For instance, we can find coherent probabilities “closest” to those provided by the experts (see Refs 43 and 44) and we can recalibrate judgments using performance on almanac questions (see *Eliciting Subjective Probability Distributions from Groups*, and Refs 27 and 45). Aggregation methods are discussed extensively in the article titled *Bayesian Aggregation of Experts’ Forecasts* in this encyclopedia.

INTRODUCTION

When eliciting uncertainty assessments from a group, the main problem is that of aggregation: how do we take potentially different assessments and obtain a single coherent assessment from them. There are many different approaches that could be adopted. Cooke [1] suggested that any methodology should conform to a set of five principles: reproducibility, accountability, empirical control, neutrality, and fairness. To ensure that the process is reproducible, it must be possible for a third party to reproduce all calculations. For accountability, the expert source of each input must be identified. Without some form of empirical control, it is difficult to assess the credibility of expert opinion. Neutrality means that the method adopted should encourage experts to state their true opinions. Finally, each expert should be treated equally *a priori*, that is, in the absence of evidence to the contrary. These principles apply largely to the general framework in which an aggregation technique is applied. However, they also have some implications for the structure of the mathematical form of the aggregation rule to be used.

Alongside Cooke's principles, one can consider mathematical requirements that an aggregation rule should satisfy [1,2]. We mention the two main possible desirable properties for an aggregation rule here.

- Marginalization is the process whereby we replace two disjoint events by the union of those two events, so that the probability coherently assessed for the union is the sum of the probabilities for the two events. An aggregation rule has the *marginalization property* if the same marginal aggregated probabilities are obtained when either marginalizing the individual expert probabilities first and then aggregating them, or aggregating the individual probabilities first and then marginalizing the aggregated probabilities. Intuitively, this means that the aggregated probabilities should not depend on the way in which the events have been grouped together.
- An aggregation rule has the *independence preservation property* if when all experts assess A and B as being independent the resulting aggregated assessment makes A independent of B .

It would be desirable if the function that aggregates the experts' assessments to a single distribution had both of the above properties. Unfortunately it can be shown that an aggregation rule cannot have these two properties [1,2]. Hence, we have to decide which is preferable.

Mathematical combination methods are broadly divided into two types: Bayesian methods and pooling methods. These are discussed below. In addition, we discuss issues arising from interaction of experts and the possibilities of behavioral aggregation. In the text below we distinguish between the roles of the expert and of the analyst. The latter is assumed to be conducting the study on behalf of a decision maker.

BAYESIAN APPROACHES

A Bayesian updating scheme is a natural way to take account of data from multiple experts [3–5]. This was first proposed by

Morris [6] (see also Clemen and Winkler [7] for details of this study). A key feature of Bayesian schemes is that the expert opinion is regarded as data. The analyst has to play the role of a metaexpert [8–10] by specifying his own prior distribution and also the likelihood of data from the set of experts (which potentially conflicts with Cooke’s principle of treating experts equally *a priori*, and also means that the analyst plays the role of an expert).

Suppose that n experts provide information separately to an analyst regarding some event or quantity of interest θ , so that this elicited information can be presented as a distribution $f_i(\theta)$ from each expert i . Then the analyst first uses Bayes’ theorem to update his own prior distribution $f(\theta)$ as follows:

$$f(\theta | D) \propto f(\theta)f(D | \theta),$$

where $D = \{f_1(\theta), \dots, f_n(\theta)\}$ is the set of the experts’ elicited distributions, and the likelihood function associated with the expert’s information is shown by $f(D | \theta)$.

This general rule can be used for the aggregation of any kind of information, such as the combination of point estimates and the aggregation of individual probabilities or probability distributions (see O’Hagan *et al.* [11] and references therein for details).

In practice, this approach is frustratingly complex and difficult to implement. The analyst needs to conduct a very sophisticated elicitation exercise on his prior distribution $f(\theta)$ and construct $f(D | \theta)$, which formulates the prior beliefs about what the experts are going to tell him, conditional on the true value of θ [11]. Clemen and Winkler [7] stressed that the likelihood function must account for the precision and bias of the individual information and it must also be able to model dependence among the experts’ elicited information.

Owing to this difficulty in assessing an appropriate likelihood function, considerable effort has gone into finding some models for aggregating single probabilities [4,12] and probability distributions [13]. Clemen and Winkler [7] and O’Hagan *et al.* [11] provide a review of a number of these models.

While Bayesian methods for aggregating expert judgment have been proposed, few have been applied in practice [1]. One exception to this is the model, proposed independently by Mosleh and Aspostolakis [14] and Winkler [15], for combining point estimates. Using the above notation, a method is proposed for assessing $f(D | \theta)$. Mosleh and Aspostolakis [14] suggest two models: one with additive errors and one with multiplicative errors.

For additive errors, it is assumed that the experts’ assessment, $f_i(\theta)$, can be modeled as $f_i(\theta) = \theta + \epsilon_i$. These errors are modeled as multivariate normal with mean μ_i and standard deviation σ_i . The analyst must provide an estimate for μ_i and σ_i , which reflects his assessment of the experts’ bias and accuracy. The likelihood function, $f(D | \theta)$, is simply the value of the normal density with mean $(\theta + \mu_i)$ and standard deviation σ_i . Alternatively, the multiplicative model assumes θ_i is log-normal and that $\theta_i = \epsilon_i\theta$. This is the same as the additive model after the assessments have been logged.

Where multiple experts are used, it seems reasonable to assume that dependency may exist between the different experts. This can be modeled using a normal or log-normal likelihood. However, this will substantially increase the burden on the analysts as they must assess a covariance matrix for the experts’ assessments.

As mentioned above, this approach assumes that the analyst is able to make assessments on the experts. This conflicts with the principle of equality *a priori*.

Other Bayesian approaches include that of Jouini and Clemen [16] which uses copulas (for definition of copula function refer to Dall’Agilo [17]) to construct a multivariate distribution (likelihood function) as a function of the experts’ elicited probability distributions. They also show how this copula-based joint distribution can be used in the Bayesian framework for aggregating expert information; see also Clemen and Winkler [7] for more details.

POOLING METHODS

Pooling methods are simple mathematical combination rules that are straightforward and widely used in practice. The two main approaches are the linear opinion pool and the logarithmic opinion pool. Letting $f_i(\theta)$, $i = 1, \dots, n$ represent the i th expert's probability distribution and w_i to be the weight attached to the i th expert's opinion ($w_i > 0$, $\forall w_i$ and $\sum_{i=1}^n w_i = 1$) then a *consensus distribution* $f(\theta)$ can be obtained as some function of the experts' distributions $D = \{f_1(\theta), \dots, f_n(\theta)\}$ in the following ways:

Linear Opinion Pool. This combination method is the weighted arithmetic mean of the densities given by $f(\theta) = \sum_{i=1}^n w_i f_i(\theta)$. The analyst might give equal weight to each expert by taking $w_i = 1/n$, or choose weights in terms of the experts' expertise. There are various ways of assigning weights [1,11,18], and we discuss two specific methods below. This is the only combination method that satisfies the marginalization property mentioned above.

Logarithmic Opinion Pool. This is a weighted geometric mean of the densities $f(\theta) = k \prod_{i=1}^n f_i(\theta)^{w_i}$, where k is the normalizing constant (a constant to ensure that the combined density integrates to 1). This method, unlike the linear opinion pool, does not satisfy the marginalization property but it does satisfy the independence preservation property mentioned above, and also a more general property called the *external Bayesian* principle. This principle tells us how an analyst updates the combined distribution when new information becomes available [3–5,19].

As discussed by O'Hagan *et al.* [11], the linear and logarithmic opinion pools lead to quite different aggregated distributions. One particular problem of the logarithmic pool is that when one expert believes an event to be impossible, then the aggregated opinion also says that it is impossible. Hence the logarithmic pool tends to concentrate probability very

highly on events for which there is consensus that they are not improbable. The linear opinion pool is widely used in practice, but logarithmic opinion pool is largely ignored because of unrealistically strong aggregated opinions.

Performance-Based Weighting

The main problem with the use of linear opinion pool is that of determining the weights. One way of doing this, which is consistent with the general principles discussed at the start, is to simply give equal weight to each expert. This method is widely used in Ortiza *et al.* [20], but is unsatisfactory because it does not allow us to use extra information that we might learn during elicitation about the experts. This extra information could be used to apply different weights without being inconsistent with the principle of treating the experts equally *a priori*.

There are two reasons why one should be interested in finding *informative weights* (that is, weights that are not just assigned uniformly). First, there may be differing levels of expertise between experts. Second, and more significantly, there may be considerable differences in the ability of subject matter experts to assess uncertainties.

Cooke's classical method gives a method for deriving weights based on the experts' performance in assessing distributions for *seed variables*, which are quantities whose true value is known to the analyst but not to the experts. The weight is determined from two measurements of expert performance on the seed variables. The first is a measure of calibration, and the second, of information. An expert is empirically calibrated if, upon examining those events for which the expert has assessed $p\%$ chance of occurrence, it turns out that $p\%$ actually occur. In the classical method this is assessed by judging how often the seed variables fall between the expert-specified 5%, 50%, and 95% quantiles. An expert's informativeness measures how narrow the uncertainty bands are, with higher informativeness associated with narrower bands. It is measured using the Kullback–Leibler distance between the expert distribution and

a uniform distribution covering the convex hull of all expert assessments. The expert's weight is determined by a combination of the calibration and information measures, judged relative to those of other experts. Experts who perform poorly with respect to the whole group may be assigned zero weight [1].

The weighting scheme proposed by Cooke [1] is asymptotically strictly proper, which means that an expert will achieve maximal weight by truthfully expressing his or her subject probability distribution (if the number of seed variables is large enough). Because of this, the classical method can be claimed to at least partially achieve the principle of neutrality mentioned above.

Cooke and Goossens [21] presented evidence that the Cooke's method produces better elicitation than simple equal weighting of the experts. O'Hagan *et al.* [11] reported that a relevant factor is neglected in the Cooke's method, which is the degree of correlation between experts. They concluded that groups of similar experts will receive too much weight, and that minority views will be underrepresented (see Genest and Zidek [5] and Clemen and Winkler [7,22] for more detailed reviews and discussion of opinion pooling).

One drawback of Cooke's method is that the scoring rule is only "asymptotically" proper. This means that the facilitator may have to ask a large number of questions in order to penalize potential game playing by experts. A recent improved method developed by Wisse *et al.* [23] gives a proper scoring rule that uses moments instead of quantiles. A loss function ϕ is defined as

$$\phi(a_1, \dots, a_n) = \sum_{j=1}^n c_j (x_j - a_j)^2,$$

where $a_1, \dots, a_n$ are the expert's assessed expectations of $X_1, \dots, X_n$ and x_j is the realization of variable X_j . A positive scaling variable, c_j is used to bring each quantity to a common monetary scale. As ϕ is a loss function, the most desirable expert is that which provides the smallest ϕ .

To develop a weighting scheme using the ϕ function, $\phi_1, \dots, \phi_n$ is calculated for

n experts. A cut-off value α is chosen such that any expert with $\phi \geq \alpha$ is given a weight of zero. Each of the remaining experts is assigned a score $\alpha - \phi_i$, which is normalized to give each expert an individual weight. α is chosen using optimization so that the loss of the combined experts is minimized. Wisse *et al.* [23] prove that the unnormalized weight of each expert is a proper scoring rule. While this method uses moments rather than quantiles, it is proposed to move between moments and quantiles using the simple Pearson–Tukey formula.

Performance of Mathematical Aggregation

Unfortunately, there is little literature on the performance of mathematical aggregation methods for probability distributions. We briefly report some important findings from these studies.

Clemen [24] argued that in the methods based on combining point estimates, the equal-weighted linear pool performs as well as more complex weighted averages. In addition, he concluded that the average generally performs almost as well as the best individual forecaster [11]. In a practical study by Winkler and Poses [25], the authors concluded that the best combination was an average of the two most experienced experts and also the least similar pairing.

The general message of the literature is that simple aggregation methods work well in comparison with more complex methods. It is clear that more sophisticated methods can beat a simple equal-weighted linear pool, but the conditions under which this improved performance can be achieved are not clear [11,25].

Cooke and Goossens [21] report very positive results with the classical method. They considered more than 20 applications including nuclear safety, volcanoes, dams, infectious diseases, pollution, and many others. Their findings show that the performance-weighted average generally calibrated as well as or better than either the best individual expert or the equal-weighted average on the seeding variables. These results support the idea that more complex methods might be justified in practical elicitation with real experts. In particular,

experts should be carefully chosen, to obtain good coverage and minimal redundancy, and should be given training in the elicitation techniques to be used; see also Cooke and Goossens [26] for more applications.

BEHAVIORAL AGGREGATION

The behavioral approach aims to generate agreement among the experts through interaction in order to share and exchange knowledge, information, and interpretations between themselves, which will cause them to reconsider their own assessments. This *may* lead to a consensus. If a single distribution is required, then the individual distributions may be combined using a mathematical approach or a consensus distribution may be sought. Such a consensus will naturally involve face-to-face group meetings via discussion and debate, interaction using computers, or sharing of information in some other way to achieve an agreement between the experts. In these situations the role of the facilitator becomes more important.

In general, these methods are not prescribed step-by-step methods but they can be flexible depending on the situation. There are some specific and controlled forms of interaction between the experts. These include the Delphi method, nominal group techniques, and Kaplan's approach.

The *Delphi method* can be applied to various kinds of group judgment and decision making. To elicit a group consensus probability distribution, the method proceeds by first eliciting the experts' assessments separately, then sharing each expert's opinions with all the other experts along with the explanation of that expert's reasoning. The experts then revise their probabilities by considering the new information they have received. This is an iterative process and it might stop when the experts' assessment have converged after a few rounds; otherwise one of the mathematical aggregation methods can be used to combine their assessments (for more details see Linstone and Turoff [27], Pill [28], and O'Hagan *et al.* [11] and references therein).

The *nominal group approach* is a variant of the Delphi method. In this method, each

expert presents her opinions to the group. The group then discusses these judgments with the help of the facilitator, and accordingly experts may revise their assessments [29]. DeGroot [30] gave another modification to this method by proposing that each expert revises her opinion by applying a linear opinion pool to all the experts' distributions, with weights that reflect the importance that each pool member puts on the opinions of each of the other participants.

The facilitator gets much more authoritative roles in the *Kaplan method*. Kaplan [31] believes that the emphasis of group elicitation should be on aggregating the experts' evidence rather than their views. The experts first present and discuss their information about the uncertain quantities in a group meeting. The facilitator then uses this information to deduce a probability distribution to present to the experts. The facilitator must obtain assurance from the experts that information has been interpreted correctly in the proposed distribution. This method is used in probability risk assessment of nuclear reactors, helicopter equipment, and space shuttle [31].

Performance of Behavioral Methods

O'Hagan *et al.* [11] reported that much of the evidence relating to behavioral aggregation has dealt with decision making or point estimation, rather than probability elicitation. In addition, the findings in the literature are generally again that the group often performs less well than a simple average of the individual judgments [32–35]. However, Reagan-Cirincione [36] finds that small group elicitation can outperform their best individual member if the elicitation combines the following three features: impartial facilitation that is responsive to the potential for biases in the group; a well-designed protocol that involves careful structuring and decomposition of the elicitation task; and continuous feedback via computer technology of the implications of the experts' judgments.

Clemen and Winkler [7] reported that there is no best method of combining expert opinion that would apply to all situations. They present several studies that attempt

to compare mathematical and behavioral methods, the results of which are mixed. Phillips [37], based on some experiments, concluded that the consensus distribution method is preferable to mathematical aggregation methods.

To choose the right method in behavioral aggregation, one should consider the type of interaction (face-to-face, via computer, anonymous); the nature of interaction (e.g., sharing information); the possibility of individual reassessment after interaction; and the role of the assessment team (e.g., facilitators). If these methods are not successful in deducing a single consensus distribution for all experts, then a mathematical aggregation may be applied.

DISCUSSION

A variety of methods have been discussed above. The choice between them depends on many “soft” factors. In public sector decision making there is a need for traceable methods that avoid biases and embrace diversity of views within the process. When the need for process validation is less, as might be the case for example in private corporations, then simpler methods may be more cost effective. In this article we have not addressed the issue of how to elicit information from individual analysts. Clearly, when eliciting information from individual experts, whether for aggregation or not, this should be done in ways that minimize known biases such as availability, anchoring, noninformativeness, and so on. In practice, combinations of behavioral approaches and mathematical aggregation may be used, for example by using small groups to help structure the modeling and hence to determine what the appropriate variables are on which further elicitation will take place.

Minas Gerais, Brazil

INTRODUCTION

The first versions of *ellipsoidal algorithms* (EAs) have been proposed by Shor [1] and Yudin and Nemirovskii [2], based on the idea of generating outer ellipsoidal approximations for convex polytopes. In 1979, Khachiyan [3] employed the ellipsoid method for proving, for the first time, that linear programming problems could be solved in polynomial time. This important theoretical result attracted the attention of the optimization theory community to the EAs [4,5], and much research had been carried out on theoretical issues related to these algorithms in the years that followed [6–15]. However, although it has polynomial-time upper bound for convergence, the EAs have been found to present poor actual convergence rates. Owing to this issue, the EAs have never replaced the simplex algorithm for linear problems. After the introduction of EAs, another family of optimization algorithms, called *the interior point algorithms*, with polynomial-time upper bound for convergence has been developed, which can solve linear problems with competitive actual convergence rates, and are now replacing the simplex methods in several practical contexts [16–19]. Todd [20] presents a perspective of this history, which involves the simplex algorithm, EA, and interior point methods.

However, due to its convergence robustness (the guaranteed convergence to the global optimum of quasi-convex problems), capability to deal with nonsmooth functions, transparent handling of constraints, and

analytical simplicity, the EAs have kept a long-standing relevance in the optimization of nonlinear problems of medium-scale size (up to some dozens of variables and constraints). Several results related to optimization of nonlinear problems can be found, for instance, in the fields of automatic control theory [21–32], computational intelligence [33,34], and electromagnetic device design [35–37]. EAs continue to be employed for the purpose of deriving theoretical results in optimization theory: for instance, in the proof of convergence of algorithms for combinatorial problems [9,38,39], in deriving new algorithms [40], and in complexity analysis [41,42]. For linear programs and their relation with the ellipsoid method, the reader is referred to an extensive appendix given in Chvátal [43].

The goal of this article is to present the working principles behind the EAs. The basic EA is introduced in a constructive manner, and an enhanced version with faster convergence is motivated and presented. The article is organized as follows:

- The classes of problems for which the EAs are guaranteed to converge to the exact solutions (linear problems, convex problems, and quasi-convex problems) are stated.
- The general principle of *cutting-plane branch-and-cut* operation, that is valid for such classes of problems, is presented.
- The basic EA is presented, as an instance of such principles, and the convergence properties of this version of EA are discussed.
- The basic EA is reformulated, with the inclusion of the *deep cuts*, which accelerate the convergence. Specific forms of deep cuts that can be applied to linear- and convex problems are presented.
- Some further implementation issues related to EAs are briefly discussed, and some references are indicated.

MOTIVATION OF ELLIPSOIDAL ALGORITHMS

Consider the following inequality-constrained optimization problem:

$$\begin{aligned} x^* &= \arg \min_x f(x) \\ \text{subject to: } &\begin{cases} g(x) \leq 0 \\ x \in \mathcal{B}. \end{cases} \end{aligned} \quad (1)$$

In this expression, $x \in \mathbb{R}^n$ denotes the decision variable vector, $f(\cdot) : \mathbb{R}^n \mapsto \mathbb{R}$ denotes the objective function, $g(\cdot) : \mathbb{R}^n \mapsto \mathbb{R}$ denotes a function that means the “maximal violated constraint”, and $\mathcal{B} \subset \mathbb{R}^n$ denotes a “bounding box” that defines upper- and lower bounds for the admissible values of the decision variable values

$$\mathcal{B} \triangleq \left\{ x \mid \begin{bmatrix} -I \\ I \end{bmatrix} x + \begin{bmatrix} \underline{x} \\ -\bar{x} \end{bmatrix} \leq 0 \right\}, \quad (2)$$

where $\underline{x} \in \mathbb{R}^n$ stores the decision variable lower bounds and $\bar{x} \in \mathbb{R}^n$ stores the decision variable upper bounds. The function $g(\cdot)$ represents a short statement of a set of constraint functions

$$g(x) = \max \{g_1(x), g_2(x), \dots, g_m(x)\}, \quad (3)$$

which makes the following equivalence hold:

$$g(x) \leq 0 \Leftrightarrow \begin{cases} g_1(x) \leq 0 \\ g_2(x) \leq 0 \\ \vdots \\ g_m(x) \leq 0 \end{cases}. \quad (4)$$

The α -sublevel sets of functions $f(x)$ and $g(x)$, denoted respectively by $\mathcal{F}_\alpha$ and $\mathcal{G}_\alpha$, are defined as

$$\mathcal{F}_\alpha \triangleq \{x \mid f(x) \leq \alpha\} \quad \text{and} \quad \mathcal{G}_\alpha \triangleq \{x \mid g(x) \leq \alpha\}. \quad (5)$$

The feasible set $\mathcal{S}$ that contains the decision variable vectors which satisfy all constraints is given by

$$\mathcal{S} = \mathcal{G}_0 \cap \mathcal{B}. \quad (6)$$

Three particular classes of problems are of interest here, since the EAs are suitable to deal with problems within such classes:

- ($\mathcal{P}_1$) Linear problems: $f(x) = cx$ and $g(x) = \max \{Ax - b\}$, with $c \in \mathbb{R}^{1 \times n}$, $A \in \mathbb{R}^{m \times n}$, and $b \in \mathbb{R}^{m \times 1}$.
- ($\mathcal{P}_2$) Convex problems: $f(x)$ and all $g(x)$ are convex functions.
- ($\mathcal{P}_3$) Quasi-convex problems: $f(x)$ and all $g(x)$ are quasi-convex functions.

Convex functions are defined by the relation

$$\phi(x) \text{ is convex} \Leftrightarrow \phi(\lambda x_1 + (1 - \lambda)x_2) \leq \lambda \phi(x_1) + (1 - \lambda)\phi(x_2) \quad (7)$$

for any $x_1, x_2 \in \mathbb{R}^n, 0 \leq \lambda \leq 1$. Quasi-convex functions are defined by

$$\begin{aligned} \phi(x) \text{ is quasi-convex} &\Leftrightarrow \\ \Phi_\alpha \text{ is a convex set } &\forall \alpha \in \mathbb{R} \end{aligned} \quad (8)$$

in which Φ_α is the α -sublevel set of $\phi(x)$. It should be noticed that linear problems are also convex problems, and convex problems are also quasi-convex problems:

$$\mathcal{P}_1 \subset \mathcal{P}_2 \subset \mathcal{P}_3. \quad (9)$$

All problems within class $\mathcal{P}_3$ (and consequently within classes $\mathcal{P}_1$ and $\mathcal{P}_2$ also) are endowed with the properties that any sublevel set $\mathcal{G}_\gamma$ is convex, and any sublevel set $\mathcal{F}_\alpha$ is convex. As the intersection of convex sets is a convex set, the sets $\mathcal{G}_\gamma \cap \mathcal{B}$ and $\mathcal{G}_0 \cap \mathcal{F}_\alpha \cap \mathcal{B}$ are also convex. The convexity of these sets is the key property that allows a cutting-plane branch-and-cut procedure that is employed within the EA. The following facts are relevant for allowing such procedures:

- Any point $x_k \in \mathcal{B}$ is on the boundary of the sets $\mathcal{F}_\alpha$ and $\mathcal{G}_\gamma$, for $\alpha = f(x_k)$ and $\gamma = g(x_k)$.

Figure 1. Cutting-plane branch-and-cut operations. The contour lines of the constraint functions g_1 , g_2 , and g_3 are depicted with thin dashed lines. The contour lines of the objective function f are depicted with thicker dashed closed lines. The feasible set is delineated by a thicker continuous closed line with three corners. A cutting plane on the feasible point x_1 would have a normal vector η_f , which is the normal vector of a contour curve of the objective function. A cutting plane on the infeasible point x_2 would have a normal vector η_g , which is the normal vector of the contour curve of the maximally violated constraint function. The point of optimum, x^* , is always kept after any cut that follows such rules.

- The convexity of the sets $\mathcal{F}_\alpha$ and $\mathcal{G}_\gamma$ implies that they have supporting hyperplanes on the point x_k , such that

$$\begin{aligned} \eta_f^T(x - x_k) &\leq 0 \quad \forall x \in \mathcal{F}_\alpha \\ \eta_g^T(x - x_k) &\leq 0 \quad \forall x \in \mathcal{G}_\gamma \end{aligned} \quad (10)$$

where η_f denotes a unitary vector normal to the supporting hyperplane of set $\mathcal{F}_\alpha$ and η_g denotes a unitary vector normal to the supporting hyperplane of set $\mathcal{G}_\gamma$.

The search for the point x^* starts with the only *a priori* information that $x^* \in \mathcal{B}$. A branch-and-cut algorithm can be employed in order to sequentially discard the portions of the set $\mathcal{B}$, such that the search continues on the remaining portions of that set, until a confidence region is small enough to guarantee that any point inside it is a reasonable approximation of x^* . The cutting-plane branch-and-cut algorithm is based on the idea that if one is able to compute a vector η_f and a vector η_g in any point x_k then, after this computation, it is possible to discard the points belonging to a semispace at one side of the cutting plane:

- In the case of infeasible x_k (in this case $\gamma > 0$), discarding the region where $\eta_g^T(x - x_k) > 0$ holds would take off a portion of the space composed of only infeasible points (since such points would be on the boundary of a set $\mathcal{G}_{\bar{\gamma}}$ with $\bar{\gamma} > \gamma$).
- In the case of feasible x_k (in this case $\gamma \leq 0$), discarding the region where $\eta_f^T(x - x_k) > 0$ holds would take off a portion of the space composed of points having objective function values higher than α (since such points would be on the boundary of a set $\mathcal{F}_{\bar{\alpha}}$ with $\bar{\alpha} > \alpha$).

The cutting-plane branch-and-cut operations are illustrated in Figure 1.

In the following section one kind of *cutting-plane branch-and-cut* procedure that can be used to solve problems of classes $\mathcal{P}_1$, $\mathcal{P}_2$, or $\mathcal{P}_3$ is discussed. The basic EA is presented, in the sequence, as a specific instance of such procedures.

Cutting-Plane Branch-and-Cut

Consider an optimization problem defined in expression (1) belonging to the class $\mathcal{P}_3$ (a quasi-convex problem). A *cutting-plane branch-and-cut procedure* that produces a

Figure 2. Four successive steps of the cutting-plane branch-and-cut procedure. The contour curves of a convex objective function are represented with dashed closed curves. In all part figures, a cutting plane is introduced on x_k , and the semispace that is excluded is shaded. The unshaded part is the remaining portion of Ω_k after the semispace exclusion.

sequence of points $[x_k]_{k=0}^{\infty}$, which, under certain conditions, converges to the solution x^* of problem (1) can be stated as in Algorithm 1. The idea of Algorithm 1 is to start the search with the information that x^* is located inside the set $\Omega_0 = \mathcal{B}$. In each step, the evaluation of a vector η_k brings new information about a region in which x^* could not be located—a nonoptimality region. The set Ω_{k+1} is calculated by discarding the intersection of Ω_k with such nonoptimality regions.

In each step, the set Ω_k has a “confidence region,” in which the optimum x^* is known to reside. The point x_k is chosen in each step as a “center” of the current confidence region Ω_k , as an attempt to get a maximal average volume-discarding rate along the algorithm iterations. A precise meaning must be attributed for “center,” in any realization of Algorithm 1. Few steps of the cutting-plane branch-and-cut procedure are illustrated in Figure 2.

Algorithm 1. Cutting-plane branch-and-cut procedure.

- 1: $k \leftarrow 0$
- 2: $\Omega_k \leftarrow \mathcal{B}$
- 3: **while not** stop criterion reached **do**
- 4: Choose a point $x_k \in \Omega_k$, such that x_k is located at “the center” of Ω_k
- 5: $\alpha \leftarrow f(x_k)$
- 6: $\gamma \leftarrow g(x_k)$
- 7: **if** $\gamma > 0$ **then**
- 8: $\eta_k \leftarrow \eta_g(x_k)$
- 9: **else**
- 10: $\eta_k \leftarrow \eta_f(x_k)$
- 11: **end if**
- 12: $\Omega_{k+1} \leftarrow \Omega_k / \{x \mid \eta_k^T \cdot (x - x_k) > 0\}$
- 13: $k \leftarrow k + 1$
- 14: **end while**

Define δ_k as the difference:

$$\delta_k = x^* - x_k. \quad (11)$$

It is expected that as the size of Ω_k becomes smaller, δ_k will also become smaller. Depending on the rule that is employed to choose x_k , it may be possible to guarantee that $\|\delta_k\| \rightarrow 0$, which would mean that the sequence $[x_k]_{k=1}^\infty$ converges to x^* .

The following sections discuss the realization issues of steps 4, 8, 10, and 12 of Algorithm 1.

Computing η_g and η_f . In the most general case of problems of class $\mathcal{P}_3$, the computation of η_g or η_f would require a local computation of the level set of function $f(\cdot)$ or $g(\cdot)$ (using for instance a level set method), followed by the computation of a normal vector to this level set. In particular cases, there are more straightforward ways for determining η_k :

- If the functions $f(\cdot)$ and $g(\cdot)$ are differentiable, then η_f and η_g are given by

$$\begin{aligned} \eta_f(x_k) &= \nabla f(x_k), \\ \eta_g(x_k) &= \nabla g(x_k). \end{aligned} \quad (12)$$

- If the functions $f(\cdot)$ and $g(\cdot)$ are convex (which means that the problem is of class $\mathcal{P}_2$, or convex), then η_f and η_g are given by

$$\begin{aligned} \eta_f(x_k) &= \nabla_s f(x_k), \\ \eta_g(x_k) &= \nabla_s g(x_k), \end{aligned} \quad (13)$$

where the notation $\nabla_s(\cdot)$ stands for a subgradient of the argument function.

- If the function $f(\cdot)$ is linear and $g(\cdot)$ is the maximum of affine functions (which means that the problem is of class $\mathcal{P}_1$, or linear), then η_f and η_g are given by

$$\begin{aligned} \eta_f(x_k) &= c^T, \\ \eta_g(x_k) &= A_i^T, \quad A_i x_k - b_i \geq A_j x_k - b_j \quad \forall j = 1, \dots, m, \end{aligned} \quad (14)$$

where A_i and b_i denote the i th row of matrices A and b .

Storing Ω_k and Choosing x_k . The problems of storing the set Ω_k and determining x_k as a “center” for such sets are interrelated. The initial set, $\Omega_0 = \mathcal{B}$, has the form of a box-constraint defined by Equation (2). Each step with a semispace exclusion action inserts a new constraint of the form $\eta_k^T x - \eta_k^T x_k \leq 0$. After k steps, the set Ω_k is given by

$$\Omega_k = \left\{ x \mid \begin{bmatrix} -I \\ I \\ \eta_1^T \\ \eta_2^T \\ \vdots \\ \eta_k^T \end{bmatrix} x + \begin{bmatrix} \frac{x}{2} \\ -\frac{x}{2} \\ \eta_1^T x_1 \\ \eta_2^T x_2 \\ \vdots \\ \eta_k^T x_k \end{bmatrix} \leq 0 \right\}. \quad (15)$$

While the center of the box Ω_0 can be determined by the simple relation $x_0 = \frac{x+\bar{x}}{2}$, finding x_k for $k \geq 1$ is a more involved problem. There is no longer an explicit representation of Ω_k as a convex combination of known vertices. The task of finding such a “center,” therefore, becomes increasingly difficult as k grows, since the constraint matrix receives one additional row per iteration.

An issue must be discussed at this point: comparing the set Ω_k , as stated in Equation (15), with the feasible solution set of a linear problem (a problem of class $\mathcal{P}_1$), which is given by $Ax - b \leq 0$, it becomes evident that both sets have a similar structure. The problem of finding a x_k associated to an Ω_k is similar to a problem of finding a feasible point for a linear problem. Therefore, the following points are suggested:

- In the case of linear problems, it makes no sense to use Algorithm 1 with such direct formulations, storing the set Ω_k via a representation like Equation (15), and calculating x_k from that representation. The reason is that the problem of finding x_k would become eventually more difficult than the original problem, and a solver for linear problems would be still necessary for solving it. Therefore, in the case of linear problems, Algorithm 1 only makes sense along with a kind of implicit representation of the set Ω_k , in order to store the information about each new cut without an exhaustive description as in Equation

(15). Such an implicit representation should also lead to a straightforward computation of a “center” x_k , in order to avoid reaching a subproblem that becomes as difficult as the original problem. The idea of the “centers” in the primal feasible-path versions of the *interior point methods* can be interpreted as an implicit encoding of progressive cuts that are added in each iteration (see **Basic CP Theory: Search**).

- In the case of nonlinear convex or quasi-convex problems (problems belonging to $\mathcal{P}_2/\mathcal{P}_1$ or $\mathcal{P}_3/\mathcal{P}_1$), finding x_k inside Ω_k can be interpreted as a sequence of linear feasibility problems, which replaces the original problem (1). This can be useful only if each linear feasibility subproblem is easier than the original problem. This is indeed the case of any problem that is suitable for being solved via the cutting-plane methods. The traditional cutting-plane methods promote an outer linear approximation of the nonlinear feasible set of increasing precision around the point of optimum. Algorithm 1, on the other hand, promotes an inner–outer approximation.

The basic EA can be interpreted as a realization of Algorithm 1, employing an ellipsoid as an implicit representation of the set Ω_k , and the ellipsoid center as the estimate of x_k .

THE BASIC ELLIPSOID ALGORITHM

It has been established that the raw cutting-plane branch-and-cut algorithm poses two main difficulties: (i) the confidence set Ω_k becomes increasingly complicated, as the number of algorithm iterations grows; and (ii) finding the center x_k of such an Ω_k becomes increasingly difficult. The basic EA can be interpreted as an attempt to solve such difficulties.

The main idea is to approximate the set Ω_k by an ellipsoid that contains it. The center of the ellipsoid becomes, in this case, an approximation for the center of Ω_k . Consider the problem (1). The basic EA begins with an

initial ellipsoid E_0 as follows:

$$E_0 \triangleq \{x | (x - x_0)^T Q_0 (x - x_0) \leq 1\}, \quad (16)$$

where $x_0 \in \mathbb{R}^n$ is the ellipsoid center and $Q_0 \in \mathbb{R}^{n \times n}$, $Q_0 = Q_0^T > 0$, is a symmetric positive-definite matrix. This ellipsoid is chosen such that $E_0 \supset \mathcal{B}$, which means that the solution x^* of problem (1) belongs to E_0 . At each iteration, the vector η_k is chosen as described in the section titled “Computing η_g and η_f .” This vector η_k defines the cut direction on the ellipsoid at each step. Using this η_k , the updates

$$\begin{aligned} x_{k+1} &= x_k - \beta_1 \frac{Q_k \eta_k}{(\eta_k^T Q_k \eta_k)^{\frac{1}{2}}}, \\ Q_{k+1} &= \beta_2 \left(Q_k - \beta_3 \frac{(Q_k \eta_k)(Q_k \eta_k)^T}{\eta_k^T Q_k \eta_k} \right), \end{aligned} \quad (17)$$

with

$$\beta_1 = \frac{1}{n+1} \quad \beta_2 = \frac{n^2}{n^2-1} \quad \beta_3 = \frac{2}{n+1} \quad (18)$$

generate a sequence of points x_k corresponding to the centers of new ellipsoids E_k :

$$E_k = \{x | (x - x_k)^T Q_k (x - x_k) \leq 1\}. \quad (19)$$

The derivation of these formulae is discussed in Refs 4 and 9.

Similar to the confidence set Ω_k in the cutting-plane branch-and-cut algorithm, all such ellipsoids E_k are guaranteed to contain the solution x^* . Geometrically, at each step, a hyperplane H_k with normal vector η_k is constructed passing through x_k . This hyperplane divides the ellipsoid E_k in half. The new ellipsoid is the smallest ellipsoid enclosing the half of E_k that contains the solution x^* . An iteration of the EA is illustrated in Figure 3. The evolution of the ellipsoids in a convex problem, from the first to the last iteration, is shown in Figure 4.

Figure 3. One step of the basic ellipsoid algorithm. The ellipsoid E_k receives a cut that passes its center, x_k , through the cutting plane normal to vector η_k . The new ellipsoid E_{k+1} has center x_{k+1} .

Convergence Analysis

The convergence rate of the basic EA is measured usually in terms of the reduction rate of the ellipsoid volume. This criterion is a direct consequence of the working principle behind the cutting-plane branch-and-cut procedure, which relies on the sequential exclusion of portions of the decision variable space, producing ultimately a sequence of smaller confidence regions, which are guaranteed to contain the point of optimum of quasi-convex problems.

In an idealized situation, the best possible case of that convergence rate for Algorithm 1 would correspond to a reduction rate of 0.5 in the confidence region volume per iteration. However, this situation cannot be reached in practice because it is not possible to guarantee that there is a “center” x_k of region Ω_k for which the region will be divided in two subregions of exactly the same volume for any cutting plane passing over it. As most of the cuts on arbitrary points x_k will discard the smaller portion of the confidence set (the reader can verify this statement by drawing the contour plot of a quasi-convex function inside a confidence region that contains the optimum, and check which regions are discarded when cutting planes are defined over random points), the following expression will hold in an average sense:

$$V[\Omega_k] \geq \frac{1}{2^k} V[\Omega_0] \quad (20)$$

where the function $V[\cdot]$ means the volume of the argument set.

In the case of the basic EA, the volume $V[\cdot]$ of the ellipsoid E_k decreases according to

$$V[E_k] = R_n^k \cdot V[E_0], \quad (21)$$

where

$$R_n = \frac{n}{n+1} \left(\frac{n^2}{n^2-1} \right)^{\frac{n-1}{2}} < 1. \quad (22)$$

The reduction ratio of the ellipsoid volume, R_n , depends on the dimension n of the space. For higher dimensions, R_n grows, and the algorithm presents slower ellipsoid volume reduction rate. The value of R_n as a function of dimension n is presented in Figure 5.

The explanation of such behavior comes from the excess of space volume circumscribed by an ellipsoid E_{k+1} in relation to the volume of the half of the former ellipsoid E_k . This issue is illustrated in Figure 6. Owing to this volume excess that is caused by the usage of ellipsoids as confidence regions, the rate of volume exclusion becomes slower when compared to an idealized instance of the cutting-plane branch-and-cut algorithm, which would present a volume compression rate of about 0.5 per iteration. As the excess becomes greater for higher dimensions, this effect causes the method to have a decreased efficiency as the problem

Figure 4. Evolution of ellipsoids generated by the basic ellipsoid algorithm in a convex problem, which has the point of optimum situated in coordinates $(0, 0)$. The part figure at the upper left shows all the ellipsoids. The sequence of part figures presents successive zooms of the region around the optimum, such that the last ellipsoid becomes visible in the lower right figure. It should be noticed that all the ellipsoids contain the point of optimum.

dimension increases. This behavior renders the basic EA ineffective even in problems of moderate dimensions. This in part explains why the EAs have received more attention, in the last years, in the context of optimization of nonlinear functions of relatively low dimension. In order to mitigate this difficulty, some variations in the method involving “deep cuts” have been developed. This is the subject of the next section of this article. Further discussions about the rate of convergence of EAs can be found in Refs 44 and 45.

Remark. A common mistake about the meaning of the convergence of the EA is the expectation that, as the volume of the ellipsoid E_k approaches zero, all points inside this

ellipsoid become arbitrary near the ellipsoid center x_k . This expectation is false because for an ellipsoid to reach a zero volume, it is enough that just one of its axes approaches zero size. Indeed, the ultimate ellipsoid in the EA very often has at least one axis that remains large (the ellipsoid in those cases tends to degenerate into a line, or into a plane, or into any other zero-measure flat). Nevertheless, even with a final ellipsoid with nonzero length axis, the center x_k usually terminates “near” the point of optimum x^* . This statement holds because not only the interior of the last ellipsoid of the sequence but also the “confidence region” is an intersection set of all the ellipsoids of the sequence $\{E_0, \dots, E_k\}$, and this intersection is usually small.

Figure 5. The volume contraction rate (R_n) of the basic ellipsoid algorithm, as a function of the space dimension n .

Figure 6. The same iteration of the basic ellipsoid algorithm presented in Figure 3, going from the ellipsoid E_k with center x_k , to the ellipsoid E_{k+1} with center x_{k+1} . The shaded areas within the ellipsoid E_{k+1} represent regions that were not contained in the half of the ellipsoid E_k that should be kept, which cause some loss of computational efficiency.

DEEP CUTS IN THE ELLIPSOID ALGORITHM

The *deep cut* procedure is obtained by using the update formulae (17), with the parameters β_1 , β_2 , and β_3 given by

$$\begin{aligned} \beta_1 &= \frac{1+n\psi}{n+1} & \beta_2 &= \frac{n^2(1-\psi^2)}{n^2-1} \\ \beta_3 &= \frac{2(1+n\psi)}{(n+1)(1+\psi)} \end{aligned} \quad (23)$$

instead of the ones stated in Equation (18). The update formulae using Equation (23)

generates a sequence of ellipsoids that contain the intersection of each former ellipsoid with a semispace H_k which does not pass through that former ellipsoid center:

$$H_k \triangleq \left\{ x \mid \eta_k^T(x - x_k) \leq -\psi \left[\eta_k^T Q_k \eta_k \right]^{\frac{1}{2}} \right\}. \quad (24)$$

Parameter ψ is called the *depth* of the cut, and represents the distance from x_k to the half-space H_k in the metric corresponding to matrix Q_k . Equation (23) is suitable for determining E_{k+1} for $-1/n \leq \psi \leq 1/n$. In the range $0 \leq \psi \leq 1/n$, the procedure leads

Figure 7. The effect of applying deep cuts. Starting from the ellipsoid E_k , (a) represents the ellipsoid E_{k+1} when a conventional cut (with no deep cut, or $\psi = 0$) is applied, (b) represents E_{k+1} for $\psi = 0.25$, and (c) represents E_{k+1} for $\psi = 0.5$.

to an accelerated convergence, since the intersection $H_k \cap E_k$ is smaller than half E_k for any $\psi > 0$ and the volume of the resulting ellipsoid E_{k+1} becomes smaller, in this range, than the volume that would result from the ordinary cut. This is illustrated in Figure 7.

The relevant questions are as follows:

- Given a problem, can a deep cut be applied within the EA?
- In a positive case, what cut depth ψ should be applied?

The answer to these questions will depend on the class of problems under consideration. In the case of quasi-convex problems (problems of class $\mathcal{P}_3$), which are the most general class of problems that can be dealt with by EAs, the application of deep cuts may lead to the loss of the solution—therefore, they should not be applied, unless the possibility of losing the optimum can be tolerated, as in the case of Refs 8 and 36. Fortunately, for problems of classes $\mathcal{P}_1$ (linear problems) and $\mathcal{P}_2$ (convex problems), there is a possibility of performing deep cuts while keeping the guaranteed convergence property [13].

Examine first the linear problems. In such problems, the cut normal vector in the case of infeasible points will have the form $\eta_k = A_i^T$, where i denotes the index of the most violated linear constraint. Notice that the feasibility of this constraint occurs for x such that

$$A_i x - b_i \leq 0. \quad (25)$$

The deep cut, instead of simply cutting the ellipsoid in its current center x_k , can directly use Equation (25), such that the maximal cut that still guarantees the constraint feasibility is applied. This can be performed by choosing ψ such that the deep cut expression

$$A_i(x - x_k) \leq -\psi (A_i Q_k A_i^T)^{\frac{1}{2}} \quad (26)$$

becomes equivalent to Equation (25). This leads to

$$\psi = \frac{A_i x_k - b_i}{(A_i Q_k A_i^T)^{\frac{1}{2}}}. \quad (27)$$

Noticing that ψ should not exceed $\frac{1}{n}$, the cut depth expression becomes

$$\psi = \min \left\{ \frac{A_i x_k - b_i}{(A_i Q_k A_i^T)^{\frac{1}{2}}}, \frac{1}{n} \right\}. \quad (28)$$

For determining the cut depth for feasible points, define $\hat{x}_k$ as the best feasible point that has been found up to iteration k (but not necessarily at iteration k). The following constraint applies to the problem optimum x^* :

$$c x^* \leq c \hat{x}_k. \quad (29)$$

This leads to the following expression for the cut depth when x_k is feasible:

$$\psi = \min \left\{ \frac{c x_k - c \hat{x}_k}{(c Q_k c^T)^{\frac{1}{2}}}, \frac{1}{n} \right\}. \quad (30)$$

In the case of problems of class $\mathcal{P}_2$ (convex problems), the following relations hold:

$$\begin{aligned} f(x) &\geq f(x_k) + \eta_f^T \cdot (x - x_k), \\ g(x) &\geq g(x_k) + \eta_g^T \cdot (x - x_k). \end{aligned} \quad (31)$$

These relations are direct consequences of convexity. In the case of x_k infeasible, the set defined by

$$g(x_k) + \eta_g^T \cdot (x - x_k) \leq 0 \quad (32)$$

strictly contains the feasible set $g(x) \leq 0$. Therefore, a deep cut that preserves the region in which Equation (32) holds can be applied. This leads to the expression

$$\psi = \min \left\{ \frac{g(x_k)}{\left(\eta_g^T Q_k \eta_g \right)^{\frac{1}{2}}}, \frac{1}{n} \right\}. \quad (33)$$

In the case of feasible x_k , taking $\hat{x}_k$ as the best feasible solution found up to iteration k , the following relation holds:

$$f(\hat{x}_k) \geq f(x^*). \quad (34)$$

The set defined by

$$\{x \mid f(x) \leq f(\hat{x}_k)\} \quad (35)$$

strictly contains the point of optimum x^* . Therefore, the deep cut given by

$$\psi = \min \left\{ \frac{f(x_k) - f(\hat{x}_k)}{\left(\eta_f^T Q_k \eta_f \right)^{\frac{1}{2}}}, \frac{1}{n} \right\} \quad (36)$$

can be applied.

FURTHER IMPLEMENTATION ISSUES

The above-mentioned points show the importance of using cuts that accelerate the ellipsoid contraction. This issue has been considered in several works:

- Dziuban *et al.* [8] Frenk *et al.* [13] study the issue of applying deep cuts, and Frenk and Gromicho [44] and Gromicho [45] study the convergence of such schemes.
- Ech-Cherif and Ecker [7], Ech-Cherif *et al.* [10], and Liao and Todd [11] discuss the application of two simultaneous cutting planes for cutting the ellipsoid.
- Kim *et al.* [12] discuss the formulation of a cut that incorporates the cut information of two successive iterations.

A very important issue that must be considered in the implementation of the EA is the numerical stability of the ellipsoid matrix Q_k . The successive application of the matrix update rule can lead to the loss of matrix positivity, which forces a premature termination of the algorithm, before reaching the user-defined stop condition. Some indications of matrix decompositions that can be used for avoiding such numerical problems are presented in Refs 4 and 6.

An extension of the EA for the case of equality constraints has been developed in Refs 14 and 15.

EMERGENCY MEDICAL SERVICE SYSTEMS THAT IMPROVE PATIENT SURVIVABILITY

LAURA A. MCLAY
Department of Statistical
Sciences and Operations
Research, Virginia
Commonwealth University,
Richmond, Virginia

INTRODUCTION AND MOTIVATION

Responding to emergency cardiac arrest 911 calls is a major focus of emergency medical service (EMS) systems. EMS systems are often evaluated by how effectively they respond to and perform care for cardiac arrest calls because (i) effective treatment is available (i.e., CPR, early defibrillation); (ii) treatment is highly time dependent [Wik *et al.* [1] states that the likelihood of survival decreases by approximately 10% for every minute of delay in providing defibrillation after the onset of cardiac arrest]; (iii) each element in the community emergency response [early access, early CPR, early defibrillation, and early advanced life support (ALS)] must be strong for optimal survival rates; and (iv) if the EMS system can respond effectively to cardiac arrest and achieve a good survival rate, the same elements will usually yield similar outcomes for other life or death conditions such as major traumatic injury or stroke. This has been well-documented by medical research [2]. The EMS response time interval is highly correlated with cardiac arrest patient survival, whereas the link between the EMS response time interval and patient survival from other types of emergency medical conditions is unclear [3].

Despite the link between EMS response and patient outcomes being well-understood, the survival to hospital discharge rate after out-of-hospital cardiac arrest is low, with approximately 5–7% of cardiac arrest patients surviving [4]. Traditional EMS

systems depend on providing ALS to 911 calls within a fixed time frame (e.g., within 8 min 59 s or less of dispatch). However, medical research indicates that for cardiac arrest calls, it is often more effective if early patient care can be initiated by a first responder [using CPR and automated external defibrillators (AEDs)] rather than wait until ALS personnel respond several minutes later [2,4,5].

Erkut *et al.* [6] first propose how to optimally locate ambulances to improve patient survival rates by locating ambulances. They motivate many of the issues described here and highlight the need for further operations research applications in the EMS domain. By optimally utilizing EMS resources, operations research has the opportunity to play a critical role in designing next-generation EMS systems that save patient lives. Operations models for next-generation EMS system design must be driven by state-of-the-art emergency medical research to improve cardiac arrest patient survival rates. This article summarizes the key issues in defining EMS systems, using scarce emergency medical resources, and assessing EMS performance when applying operations research methodologies. For further information, the reader is referred to several excellent reviews of how operations research methodologies have been applied to EMS applications [7–11].

This article is organized as follows. First, background information about EMS systems and their resources are described. Second, ways to assess EMS performance are summarized and ways to measure patient survivability when addressing how to locate ambulances at rescue stations are discussed. Many of the performance measures have applications to other problems in EMS management and design. Next, important problems in next-generation EMS design that can benefit from systematic operations research modeling and analysis are discussed. The problems discussed extend beyond the scope of location models. Next, an illustrative example illustrates some of the key issues raised with data

extracted from Hanover County, Virginia. Finally, concluding remarks are given.

EMS BACKGROUND

Even small EMS systems may use several types of resources. Optimally using these scarce resources is challenging and often counterintuitive. This section summarizes the key resources used by EMS systems, including medical units, personnel, and computer-aided dispatching (CAD) systems.

EMS Resources

Historically, many EMS departments are under the same administration as fire departments and sometimes police departments. Sharing resources with other departments not only increases the number of resources that can be leveraged to respond to emergency medical calls, but also increases the complexity of the problems facing EMS agencies.

EMS departments contain a mixture of different types medical units as well as different types of staff. Ambulances are staffed by basic emergency medical technicians (EMTs) who provide basic life support (BLS) or paramedics (EMT's) who provide ALS. In some EMS systems, there may be several types of medical units that can respond to emergency 911 calls, including ambulances, nontransport quick response vehicles (QRVs), fire engines, and even police cars (police officers can provide CPR and basic first aid; some carry AEDs). Multiple medical units may be dispatched to a single 911 call. If a nontransport unit is dispatched first (such as a QRV or fire engine), then an ambulance must also be dispatched to the call to transport the patient to a hospital. In addition, medivacs (helicopter services operated by paramedics) may also be dispatched in the event that hospital transport is required.

For decades, EMS systems have been measured according to how they respond to and care for cardiac arrest patients [3]. As a result, since the 1960s, EMS systems increasingly provide more medical care at the scene and during transport. Most rural (and some suburban and smaller urban) EMS systems

in the United States have historically relied on volunteer EMTs. Many EMS systems have shifted from BLS to ALS ambulances, and hence, from EMTs to paramedics. At least one paramedic must operate a medical unit for it to be considered an ALS.

Ambulance staff may be volunteers or paid personnel. Owing to the decline of volunteerism, EMS systems increasingly rely on paid personnel. EMS systems are composed of a mixture of EMTs, paramedics, volunteers, and paid personnel. Many fire fighters are certified as either first responders or EMTs, and hence, they can provide BLS treatment.

Treating EMS Patients

Emergency medical 911 calls are typically classified as Priority 1, 2, 3, where Priority 1 calls are life-threatening emergencies, Priority 2 calls are emergencies that may be life threatening, and Priority 3 calls do not appear to be life-threatening emergencies. There is not a universal protocol for responding to Priority 1, 2, and 3 calls, since the response depends on the types of resources as well as the characteristics and demographics of the area that the EMS system serves. One such protocol for an EMS system with both ALS and BLS units is to deploy ALS units to Priority 1 calls, either type of ambulance for Priority 2 calls, and BLS units to Priority 3 calls. In addition, since many EMS agencies are under the same administration as the fire department, fire engines (with ALS or BLS equipment) can be dispatched to Priority 1 calls to stabilize patients and to Priority 2 and 3 calls if an ambulance is not readily available. Moreover, since not all Priority 1 calls turn out to be life threatening, they may be downgraded to Priority 2 after a unit has arrived on scene. Likewise, Priority 2 or 3 calls can be upgraded. Paramedics may be required to transport Priority 1 patients to the hospital, and hence, dispatching EMTs (BLS) to a Priority 1 call to stabilize a patient would necessitate dispatching a second (ALS) ambulance to the call if the patient requires hospital transport.

The following sequence of events occurs for each emergency medical call handed by EMS agencies [9].

1. An emergency medical 911 call is made and is handled by the dispatch center.
2. The dispatch center estimates the severity of the call.
3. The appropriate vehicles are dispatched to the scene of the call.
4. Service is provided.
5. The patient is transported to the hospital, if needed.
6. The vehicle returns to service and is directed to a predetermined location (e.g., station).

Dispatch Center

The dispatch center is a vital part of any EMS system. The dispatch center or primary public safety answering point receives emergency 911 calls, and determines the appropriate response. Calls arrive at a centralized center, and emergency medical, fire, and police calls are routed to separate dispatchers. In large cities, the EMS dispatch center may be physically located in a separate building from fire and police dispatch centers. When dispatchers answer calls, they usually interface with a CAD system to collect information from the caller, including the address and nature of the calls, dispatch units to the calls, and record information regarding the treatment of the patients.

The following sequence of events is typically recorded by CAD systems.

1. A record is entered into the CAD system.
2. A unit is dispatched to the call.
3. The unit leaves the station.
4. The unit arrives at the scene.
5. The unit leaves the scene for the hospital.
6. The unit arrives at the hospital.
7. The unit leaves the hospital.
8. The unit returns to service.
9. The unit arrives at the station.

Note that if a call does not result in a trip to the hospital, then 5–7 may not be recorded. The *response time* captures the difference between when the call was received (1) or

the unit is dispatched (2) and when it arrives at the scene (4) (or the curbside, when calls are in a skyscraper). The *turnaround time* captures the difference between when the call was received (1) or the unit is dispatched (2) and when the unit returns to service (8). Note that when a call arrives at the dispatch center, it is often not recorded, and hence, times are measured relative to when a unit is dispatched to a call, making it even more difficult to truly estimate how long a patient waits for the EMS response [3].

Large cities may have proprietary CAD systems that indicate how to dynamically dispatch and relocate medical units. In all but the largest US cities, CAD systems are generally not custom-designed, since they are often purchased from outside vendors. CAD systems record information to document EMS performance measures. However, the limitation is that it is often difficult to assess performance measures that are not captured explicitly by CAD systems. For example, it is often impossible to measure the response time interval from the time that the patient collapses. Rather, the “response time interval” is usually the time from dispatch to arrival of the unit on location (which is still not necessarily the time the team is at the patient’s side). It can be difficult to interface EMS CAD systems with fire and police CAD systems, which is necessary to understand the system response characteristics if fire and police respond to EMS calls and provide patient treatment. For example, the same patient may be assigned different incident numbers in the EMS and fire CAD systems. Matching calls by address and time may also be difficult since the difference in dispatch times between the types of units may be several minutes or longer. In addition, there are problems of time synchronization between different timepieces used in the EMS system, which results in documentation errors in response time intervals and other time measures [12].

CAD systems provide a large amount of data, but the data are often problematic [11]. For example, CAD systems capture events that are recorded by dispatchers (such as when an ambulance leaves the station) and do not always reflect when the events

actually occurred. Frequently, events are missing or are obviously incorrect (such as turnaround times that are 0 or negative, and response times that take hours). In addition, many calls are canceled before a medical unit reaches the destination. Hence, patients are “not treated” for a significant proportion of calls in the CAD database.

In EMS system design, the call locations are of interest to understand the nature of the response. Many CAD systems record the location of the call as well as its coordinates using a grid or district. Ideally, a geographic information system (GIS) is used to record latitude longitude coordinates. However, this has not been implemented in all CAD systems. Using a grid or district instead can capture approximate locations and is useful for aggregating call locations; but if this grid is coarse (e.g., 5 miles $\times$ 5 miles), it may limit the approaches used to design next-generation EMS systems.

PATIENT SURVIVABILITY PERFORMANCE MEASURES

This section summarizes traditional performance measures used by operations research models to evaluate EMS systems, and proposes new performance measures for next-generation EMS systems. The performance measures in this section focus on issues involving the response to emergency medical patients. Since the response time interval is closely tied with patient survival—the ultimate goal in EMS systems—all performance measures can be modeled as a *utility function associated with the response time*. The implications and challenges for using these performance measures are discussed as they relate to EMS operations and management of CAD systems. First, standards set by EMS systems are introduced, since these standards are the basis for operations research modeling efforts.

Performance measures used by operations research models often mimic the standards set by EMS systems, which almost always measure the response time. According to Fitch [3], the most common standards for an EMS system are as follows:

1. Respond to 90% of urban (Priority 1) calls in less than 9 min,
2. Respond to 90% of rural (Priority 1) calls within 15 min,
3. Respond to 90% of wilderness (Priority 1) calls within 30 min.

According to the first standard that requires that 90% of calls are responded to in no more than 8 min 59 s, a call is considered to be covered if the response time is 8 min and 59 s, whereas a response time of 1 s longer (9 min) is not considered to be covered. However, according to the medical literature, no difference in patient outcomes would be expected between these two scenarios. Formulated as a utility, the utility is 1 when the response time t_R (measured in minutes) is less than 9 min (i.e., $u(T_R) = 1, t_R < 9$) and 0 when the response time is 9 min or longer (i.e., $u(T_R) = 0, t_R \geq 9$). For this reason, these binary standards are not optimal for measuring patient survivability rates.

As noted elsewhere, little or no guidance is given as to how to interpret these standards based on time of day or location [11,6]. For example, it is not clear if it is acceptable to have, say, 80% of Priority 1 calls responded to in less than 9 min during the day and, say, 95% of Priority 1 calls responded to in less than 9 min overnight, so long as 90% of Priority 1 calls are responded to in less than 9 min across all times. Moreover, little guidance is given as to how to define the response time interval. The response time interval typically measures the time until an ALS ambulance responds. In such cases, the response time interval does not indicate if there were earlier responders (such as BLS ambulances or fire engines) or the time when patient care was initiated, which makes it difficult to assess the true EMS system response interval.

Although patient survivability (measured as patients surviving until hospital discharge) is the ultimate goal, performance measures set by EMS systems and used by operations research models quantify proxies for patient survivability. Until recently, this was a necessary measure, since having access to large amounts of CAD data is a relatively new phenomenon that has allowed for new and more detailed modeling

efforts. The proxies for patient survivability generally have one of the following forms [9]:

- maximize the proportion of the (geographic) area that can be responded to in a fixed time frame,
- maximize the proportion of the population that can be responded to in a fixed time frame,
- maximize the expected number of calls that can be responded to in a fixed time frame.

Medical research has shed some light on effective performance measures for EMS systems. Next-generation EMS systems and operations research models for such systems must be proactive in using this information to identify operational practices and strategies that translate to better patient outcomes.

Maximizing patient survival rates can be accomplished by using medical models that relate EMS response time intervals to patient survivability in cardiac arrest patients. Four of these models are explored here, which result in four patient survivability functions, each of which can be expressed as a utility. The excellent paper by Erkut *et al.* [6] explores these issues in greater detail, and some of the analysis is reproduced here. All survival models are interpreted to assume that EMS personnel do not witness a cardiac arrest. Let S denote the patient survivability, which is assumed to represent a probability (i.e., $0 \leq S \leq 1$) or utility. All times in the following models are measured relative to the time of collapse and are measured in minutes. Note that survival in each of the following equations can be thought of more generally as a utility associated with the response time.

The first survivability model is based on a study by Larsen *et al.* [13], which performed multiple linear regression for King County in Washington. Their model for patient survivability is given by

$$\begin{aligned} S(t_{\text{CPR}}, t_{\text{AED}}, t_{\text{ALS}}) \\ = \max\{0.67 - 0.023t_{\text{CPR}} \\ - 0.011t_{\text{AED}} - 0.021t_{\text{ALS}}, 0\}, \quad (1) \end{aligned}$$

where t_{CPR} denotes the time from collapse until CPR is performed on the patient, t_{AED}

denotes the time of defibrillation, and t_{ALS} denotes the time when ALS treatment is provided.

The second survivability model is based on a study by Valenzuela *et al.* [14]. It performs logistic regression to obtain an expression for patient survivability, and it is based on data obtained from Tucson, Arizona and King County, Washington. They estimate patient survivability as

$$\begin{aligned} S(t_{\text{CPR}}, t_{\text{AED}}) \\ = (1 + e^{-0.260 + 0.106t_{\text{CPR}} + 0.139t_{\text{AED}}})^{-1}. \quad (2) \end{aligned}$$

The third survivability model by Waelwijn *et al.* [15] performs logistic regression to obtain an expression for patient survivability from the perspective of the bystander that is based on data from Amsterdam, Netherlands. In this expression, it is assumed that the cardiac arrest is not witnessed by EMS providers. Patient survivability is expressed as

$$\begin{aligned} S(t_{\text{CPR}}, t_{\text{R}}) \\ = (1 + e^{0.04 + 0.3t_{\text{CPR}} + 0.14(t_{\text{R}} - t_{\text{CPR}})})^{-1}. \quad (3) \end{aligned}$$

The fourth survivability model by De Maio *et al.* [16] uses stepwise logistic regression to estimate patient survivability using data from Ontario, Canada, with

$$S(t_{\text{R}}) = (1 + e^{0.679 + 0.262t_{\text{R}}})^{-1}. \quad (4)$$

Figure 1 illustrates the utility for the four patient survival models considered as well as the standard requiring ALS care in less than 9 min under the following assumptions:

- It takes exactly 1 min for a call to EMS to be made and an ambulance to be dispatched after the patient collapses.
- CPR is performed by a paramedic or EMT immediately upon arrival, and CPR is not performed earlier by a bystander, resulting in $t_{\text{CPR}} = t_{\text{R}}$.
- An AED is used 1 min after arrival, resulting in $t_{\text{AED}} = t_{\text{R}} + 1$.
- ALS is provided 2 min after arrival ($t_{\text{ALS}} = t_{\text{R}} + 2$).

Figure 1. Patient survival utilities as a function of response time.

Figure 1 shows the utility curves for the four patient survivability functions and the 9-min EMS standard. Figure 1 indicates that patient survival is significantly less than 1, even for response times of 0. At 9 min, patient survival is less than 10% for all the models considered, and although patient survivability beyond 9 min is positive for all the models, cardiac arrest patients are extremely unlikely to survive.

The response time interval is an important predictor for short-term patient survival. Other factors that have been identified by the medical literature that affect short-term patient survival include the age of the patient, whether a bystander is present at the time of collapse, and whether bystanders attempted CPR and defibrillation before the first responder arrives.

Although Priority 1 patients are equally likely to survive whether an ALS or a BLS medical unit responds to the call, it is important for personnel to practice medical skills in order to maintain their efficacy in treating emergency medical patients [17]. One way to maximize patient survival rates, at least in the short term, is to employ as many medical units as possible to reduce response times.

This approach would, however, result in each medical unit responding to fewer calls, and hence, each paramedic and EMT would treat few patients, which may eventually erode their proficiency to treat patients. Therefore, there are drawbacks to simply increasing the number of medical units to meet performance standards. EMS systems should ideally consider the appropriateness of the response so that ALS providers have the most opportunities to provide patient care (i.e., dispatching ALS to Priority 1 calls and BLS to Priority 2 and 3 calls).

OPERATIONS RESEARCH OPPORTUNITIES

Designing next-generation EMS systems is truly a systems issue. This section overviews several broad areas in next-generation EMS design that could benefit from operations research methodologies. All potential application areas directly or indirectly affect patient survivability. In this article, patient survivability is motivated by the problem of locating medical units at stations. However, there are a number of other EMS problems that have the potential to improve patient survival rates.

Although numerous models have been analyzed for locating ambulances at a set of stations, nearly all models focus on meeting EMS standards and proxies for patient survivability, rather than explicitly modeling patient survivability [7–9]. Recently, McLay [18], Erkut *et al.* [6], and McLay and Mayorga [19] examined how to locate medical units when focusing on patient survivability.

McLay [18] evaluates the impact of the first responder on ambulance locations, a stepping stone to evaluating patient survival. In particular, McLay [18] investigates how to locate both ALS and BLS medical units such that response time is determined by the first responder, rather than the ALS medical unit, as traditionally done in EMS systems. McLay [18] examines the effect of dispatching policies for ALS and BLS medical units to Priority 1, 2, and 3 calls to illustrate how to use and locate medical units.

Erkut *et al.* [6] illustrate the importance of explicitly linking ambulance location to patient survivability, by providing the following example. Two demand locations A and B are located 18 min apart, with three potential stations located at A, B, and X, a station exactly 9 min away from both A and B. The demand at A is 10, and the demand at B is 1. Exactly one ambulance is available. Traditional operations research models that seek to maximize the number of calls responded to in less than 9 min locate the ambulance at X, which covers the entire demand of 11. If the probability of survival is given by $\exp(-t_R)$, where t_R denotes the response time (measured in minutes), then the expected number of survivors when an ambulance is located as X is $11 \times \exp(-9) = 0.001358$, whereas the expected number of survivors when the ambulance is located at A is 10, which differs by a factor of 700 [6]. This indicates that traditional covering location models may result in arbitrarily bad patient survival rates and motivates modeling efforts that explicitly focus on patient outcomes.

Erkut *et al.* [6] apply patient survivability models reported in the medical domain (see Fig. 1) to ambulance location models using discrete optimization models (linear and nonlinear) and Monte Carlo simulation. The probability of patient survival is a function of

response time, the time to initiate CPR, pre-travel delays, and the time to defibrillation. They demonstrate the benefit of using patient survival location models using data extracted from Edmonton, Canada. They explore how patient survival affects the location of ambulance by using survivability models as the objective function in set covering and maximal coverage models that consider one type of medical unit (ALS ambulances).

McLay and Mayorga [19] propose a methodology to evaluate a class of performance measures according to their resulting patient survival rates. They focus on response time thresholds (RTTs) and the number (or fraction) of calls that can be reached in a fixed time frame (the 9-min EMS standard is a 9-min RTT). They find that RTTs can act as proxies for patient survivability performance measures. For an example with real-world data, they find that 7- and 8-min RTTs always locate ambulances such that patient survival is also optimal. Similarly 9- and 10-min RTTs result in more equitable patient outcomes, with fewer disparities between rural and urban patient survival rates. These results are counterintuitive, since medical experts often recommend an EMS response time interval of less than 4 min. An example from this paper is summarized in section titled “Illustrative Example.”

Patient survivability largely depends on issues that EMS departments have traditionally not focused on. For example, medical literature has recognized that patient survivability depends on whether bystanders initiated CPR or defibrillation. Cities that have had large-scale CPR campaigns have benefited from a large proportion of cardiac arrest patients receiving bystander CPR prior to the EMS response and, as a result, have high patient survival rates [20]. We are not aware of any operations research modeling efforts that perform a systematic analysis of the effect of CPR campaigns on EMS and patient outcomes. Such a systems approach to maximize patient survivability may identify cost-effective ways to improve patient outcomes. A number of methodologies could be beneficial, including applied probability models and simulation.

In many cities and counties, emergency medical treatment of patients extends beyond ambulances and paramedics. Increasingly, campaigns that train people to apply CPR and the deployment of AEDs in public places results in care being applied by cardiac arrest bystanders. These campaigns have resulted in significant improvement in cardiac arrest patient survival rates [4,5]. Understanding where to locate AEDs as well as identifying how many should be purchased has the potential to save lives. For example, locating AEDs in Chicago airports resulted in a 75% survival rate for ventricular fibrillation cardiac arrests (9 of 12 patients survived) as compared to a 2% cardiac arrest survival rate in the city of Chicago [20]. A relative 40–45% increase in patient survival rate has been observed after large-scale AED deployments [20].

Another avenue of research using operations research is to design better EMS standards. For example, it has been noted that response time intervals should be less than 5 min and defibrillation should occur in less than 6 min from the time of collapse [3]. McLay and Mayorga [19] challenge this assumption by applying discrete optimization models, but more analysis is needed. Applying operations research models (using simulation, agent-based modeling, and decision analysis, for example) to analyze and create new standards has the potential to improve patient survivability. For example, performance measures used by operations research models almost always depend on a response time interval standard (such as 9 min), but a little guidance or explanation is used to explain why the selected response time interval is used [11]. Investigating how new standards correlate with patient outcomes can change how EMS systems are operated. Emergency medical research has shed light on some of these EMS features, such as illustrating that ALS patient care does not result in higher patient survival rates than BLS patient care [2]. Operations research can link state-of-the-art medical knowledge to practical guidelines for responding to and treating patients. Multiple-objective decision analysis and optimization can be used to design EMS

systems that perform well across multiple criteria (such as coverage and fairness). Chanta *et al.* [21] take an important first step in investigating the issue of equity using biobjective covering location models.

Response time is almost always used to measure EMS performance. Recall that the response time interval quantifies the time between when a medical unit is dispatched and when it arrives at the scene. It has been noted that the response time interval is often measured in different ways and does not reflect the true impact on patient survival. Budge *et al.* [22] indicate that the response time interval is usually defined to measure the sum of the travel time and the pretravel delay (the time between when the ambulance is dispatched and when the ambulance departs the station). The response time interval measures the response from the EMS point of view rather than the patient point of view since it is defined relative to dispatch rather than patient collapse. Exploring uncertainties in the components of response time from the patient point of view is critical for accurately predicting patient survival. Possible methodologies to be used here include data mining, stochastic processes, and simulation.

Nearly all EMS systems locate ambulances at rescue or fire stations when the ambulances are not busy treating patients. In order to improve patient survival rates, stations must be located in areas with high population density. Therefore, cities and counties zone the land for new stations before new development occurs. Although many location models have been developed, few consider long-term issues in building rescue stations based on changing demographics, anticipated zoning, and forecasted call volumes, which requires systematic planning and analysis. Not only are stations built under uncertainty with respect to forecasts in call volume, they are built under uncertainty with respect to EMS utilization and operations. For example, future EMS systems may rely even more heavily on paid personnel (rather than volunteers), may use BLS medical units rather than ALS medical units, and are not likely to locate ambulances at all stations at once. Exploring these issues

(using forecasting and optimization models, for example) can determine the best location for a future station across a wide spectrum of operating conditions.

Optimizing dispatching protocols—in addition to locating medical units—have potentially large effects on patient outcomes. To maximize patient survival rates, it is necessary to understand when to dispatch the closest medical unit to a call and when to dispatch a farther medical unit to a call. However, little attention has been given to identifying optimal dispatching policies. Carter *et al.* [23] use a queueing optimization model to determine the locations of two EMS response areas (i.e., beats) to balance the workload between two medical units. Each medical unit is assumed to always respond to calls within its response area, if the medical unit is available. If both medical units are busy, calls are served by medical units outside of the area. Carter *et al.* [23] show that it is not always best to dispatch the closest medical unit. Jarvis [24] introduces a Markov decision process model for the hypercube queueing model for determining optimal dispatching policies for a single type of medical unit, and it is illustrated with an example that minimizes the average distance traveled when responding to a call. Additional dispatching policies are needed to dispatch multiple types of medical units (including ambulances, nontransport units, fire engines, and police cars) to multiple patient priorities. Possible methodologies for this application include simulation optimization, decision support systems, and approximate dynamic programming. Henderson [25] proposes using system status management and approximate dynamic programming for relocating ambulances.

Providing guidelines for scheduling paid personnel given uncertainty in volunteer schedules has the potential to more efficiently use EMS resources. Many EMS stations supplement volunteer personnel with paid personnel. There are many challenges for scheduling in a mixed personnel system. For example, volunteers may have scheduling commitments that they cancel more frequently than paid personnel. When a volunteer cancels, usually very little notice

is given to the EMS management. The uncertainties in volunteer schedules can be addressed by planning for the worst-case scenario (i.e., not relying on volunteers at all), therefore, assuming that only paid personnel are available. This approach is suboptimal in two ways. First, it is more costly, since it is expensive to fully utilize paid personnel and overuse medical equipment. Second, with more personnel available, paramedics and EMTs respond to fewer emergency medical 911 calls and utilize their medical skills less frequently, which degrades their level of competence over time [17]. In addition, volunteers have lower levels of job satisfaction if they treat fewer emergency medical patients and transport more patients to the hospital, and volunteers are less likely to volunteer in the future if their skills are not utilized [26]. Sampson [27] outlines several key differences between volunteer and traditional (i.e., paid) scheduling problems and notes that cost is often not the bottom line when utilizing volunteers.

Suburban and rural EMS departments are not simply smaller versions of urban EMS departments, but rather they have unique characteristics that differentiate them from urban EMS departments. Suburban and rural EMS departments are characteristic of many EMS systems throughout the nation and illustrate issues that EMS systems frequently face on a daily basis. In particular, they typically operate in areas with low population densities, are not near hospitals, and rely on volunteer staff rather than career staff. Most notably, they typically leverage several types of resources to respond to emergency medical 911 calls. For example, personnel may include volunteer and paid staff, medical units may include ALS ambulances, BLS ambulances, nontransport QRVs, and fire engines. This can be contrasted to urban EMS systems, which may only have paid staff and one type of ambulance. Therefore, suburban and rural EMS management is extremely complex, even for small EMS systems, since determining the optimal portfolio of resources may be counterintuitive. Yet, these types of EMS systems typically lack the resources to determine how to optimally allocate and use their resources.

As operations research methodologies are applied to a broad set of EMS problems and operations, new EMS features and operations research models may become apparent, leading to new application areas within next-generation EMS system design.

ILLUSTRATIVE EXAMPLE

Models that improve patient survivability ultimately focus on the response time interval, and there are many factors that affect how the response time interval is measured and how medical units are used to respond to calls. This section explores several of these factors using real-world CAD data in order to illustrate several of the issues that influence the design of next-generation EMS systems and summarizes results from McLay and Mayorga [19] using this data to locate ambulances according to patient survival rates.

This section illustrates some of the challenges in designing effective and robust next-generation EMS systems using data extracted from Hanover County, a semisuburban, semirural county near Richmond, Virginia with a population of approximately 100,000 and an area of 471 square miles. It is described as approximately 70% rural with areas of suburbs. It uses a mixture of ALS and BLS ambulances, ALS QRVs, and fire engines for treating emergency medical patients. It employs paramedics (paid personnel) and EMTs (paid and volunteer personnel). AEDs are available on all types of medical units. Hanover County has 12 fire stations and 4 rescue stations at which they can locate ambulances. It is partitioned into 12 districts that correspond to the geographic areas surrounding each of the 12 fire stations. Figure 2 shows a map of Hanover County and its fire and rescue stations.

The CAD data set contains 9710 calls for service in a 1-year period, and it includes information regarding the location, response time, and service times for all calls. The dispatcher manually enters this information, and hence, there are occasionally problems with the data. For example, in 145 of the 8232 calls in which an ambulance responds (1.8%), the time when the ambulance leaves

its station is not recorded. In 60 of the 5764 calls in which an ambulance transports a patient to the hospital (1.0%), the time when the ambulance leaves for the hospital is not recorded. In addition, the response times vary from 0 to 604 min. Both extremes reflect scenarios that need to be taken into account when performing a data analysis. To understand these response times, note that the dispatcher enters the time into the CAD system by hitting a button that records the current time, not by physically recording the current time. Many of the scenarios with response times of 0 correspond to the cases when a second ambulance voluntarily responds to a call (before dispatched), and the dispatcher later enters this response into the CAD system, resulting in identical dispatch and responding times. The scenarios with extremely large response times correspond to the cases when the dispatcher forgets to enter the responding times into the CAD system. When this omission is noted, the dispatcher corrects the missing value by entering the current time, which may be hours after the ambulance responded. All of these issues indicate that there are many real issues in interpreting CAD data, although these issues are only present in a small proportion of the CAD data entries. Working with the EMS department is necessary to truly understand what phenomena the CAD data reflect and operational issues that the EMS department faces.

The CAD data indicate that 54, 22, and 24% of calls are classified as Priority 1, 2, and 3, respectively. These priorities are determined by call characteristics, medical protocols set by the medical director, and the CAD system. Therefore, the proportions of Priority 1, 2, and 3 calls can change abruptly when medical protocols or the CAD system change. For example, prior to changes in the Hanover County's medical protocols and the CAD system, 63, 26, and 11% of calls were classified as Priority 1, 2, and 3, respectively. The call priorities are also location-dependent, since they reflect the demographics and zoning in the vicinities of the stations. On the basis of the 12 fire districts, the proportion of calls originating in each district classified as Priority 1 varied from 49 to 56% of all calls.

Figure 2. Fire and rescue stations in Hanover County, Virginia.

In a significant number of calls (11%), an ambulance is dispatched to a call, but the call is canceled before the ambulance arrives. This occurs for a number of reasons, and it occurs more frequently with high-priority calls, when multiple ambulances may be dispatched to a single call. A call is canceled for 14.2, 8.8, and 5.9% of Priority 1, 2, and 3 calls, respectively.

Improving response time to cardiac arrest patients can improve patient survival rates. It is difficult for a dispatcher to correctly diagnose a cardiac arrest over the phone, and cardiac arrest calls could be classified

as “Difficulty Breathing,” “Chest Pains,” or “Heart Problems” by the dispatcher. Not all calls with these classifications are truly cardiac arrest calls. Table 1 summarizes these call classifications by priority. Note that 24.5% of Priority 1 calls are one of these three call classifications, and hence, a large number of Priority 1 calls are potentially cardiac arrest calls. In addition, a small proportion of cardiac arrest calls could be misclassified as abdominal pain, for example, although these false negatives are difficult to identify from CAD and medical data.

Table 1. Number of EMS Calls by Classification and Priority

Classification	Priority 1	Priority 2	Priority 3
Difficulty breathing	697	160	9
Chest pains	360	159	14
Heart problems	100	14	8
All calls	4722	1925	2043

Table 2. Response Times According to District and Distance

District	All Responses			Responses ≤ 4 miles			Responses > 4 miles		
	$\bar{t}_R$ (min)	s_R	p_R	$\bar{t}_R$ (min)	s_R	p_R	$\bar{t}_R$ (min)	s_R	p_R
1	8.8	5	0.57	6.9	3.7	0.78	11.3	5.3	0.31
2	17.1	6.6	0.07	12.8	4.9	0.19	17.7	6.6	0.05
3	11.5	6.7	0.40	8.3	4.6	0.62	16.1	6.6	0.10
4	12.8	7.5	0.34	8.1	4.8	0.66	15.7	7.4	0.14
5	12.9	4.3	0.12	10.5	2.6	0.32	13.3	4.4	0.09
6	9.2	5	0.56	7.0	4.1	0.69	12.2	5.3	0.26
7	9.1	4.6	0.58	8.2	5.4	0.68	10.6	5.3	0.44
8	12.2	7.5	0.37	8.1	5.5	0.67	14.5	7.4	0.20
9	18.9	6.4	0.04	NA	NA	NA	19.5	6.5	0.03
10	8.7	5.1	0.62	8.0	4.9	0.70	10.6	5.1	0.40
11	14.2	5.5	0.11	10.6	5.3	0.38	14.2	5.4	0.10
12	15.3	4.9	0.07	11.4	2.7	0.19	16.6	4.8	0.03
Overall	10.2	5.8	0.49	7.8	4.1	0.69	12.7	6.2	0.28

The response time depends on the locations where the calls originate as well as the distances traveled. Table 2 shows the average response times ($\bar{t}_R$), the standard deviation of response times (s_R), and the proportion of calls responded to in less than 9 min (p_R) for all calls, calls when the ambulance travels 4 miles or less, and calls when the ambulance travels more than 4 miles for each of the 12 districts. The average response time is 10.2 min, which decreases to 7.8 min if an ambulance travels 4 miles or less and increases to 12.7 min if the ambulance travels more than 4 miles. Response times for all instances suggest that even when ambulances travel short distances, cardiac arrest patients are not likely to survive, which motivates using more comprehensive models and methodologies to address patient survivability.

The data set indicates that there is double response on 11% of the calls. In these calls, two ambulances are sent to the call. The first ambulance stabilizes the patient, and the second ambulance provides patient care and transports the patient to the hospital, if needed. The double response rate is 13,

7.4, and 5.7% of all Priority 1, 2, and 3 calls, respectively. The double response rate is higher on the weekends (12% of all calls) versus weekdays (10% of all calls). Since the weekends almost entirely rely on volunteer EMTs, there is likely a difference in how volunteer resources are used as compared to paid personnel. The double response rate also varies with the location where the call originates. Table 3 summarizes the number and proportion (p_D) of calls in each of the 12 fire districts for which there is double response. The most rural districts (2, 8, 9, 11) have high levels of double response as compared to suburban districts (1, 4, 7, 12).

The CAD data set indicates that 71% of calls result in a patient transported to the hospital. Understanding how an EMS system transports patients to hospitals is critical for understanding how the EMS system utilizes its resources, since patient transport time represents the majority of the ambulance service time. Table 3 summarizes the proportion (p_H) of calls in each of the 12 fire districts in which patients are transported to the hospital. In addition, Table 3

Table 3. Double Response and Hospital Call Characteristics According to District

District	Double Response	Hospital Calls		
	p_D	$\bar{t}_T$ (min)	s_T (min)	p_H
1	0.06	94	31	0.67
2	0.14	131	26	0.80
3	0.11	83	26	0.73
4	0.05	103	38	0.72
5	0.12	91	24	0.81
6	0.13	81	30	0.71
7	0.10	74	25	0.73
8	0.14	116	32	0.72
9	0.49	120	33	0.78
10	0.12	85	25	0.65
11	0.17	109	27	0.70
12	0.09	95	30	0.75
Overall	0.11	88	32	0.71

summarizes the average and standard deviation of the turnaround time (measured in minutes) when patients are transported to a hospital ($\bar{t}_T$ and s_T , respectively). Note that the average turnaround time for calls that transport patients to the hospital varies from 74 to 131 min, since the east side of Hanover County is closer to several hospitals than the west side. This motivates models for optimal dispatching policies, since an ambulance may be busy for more than 2 h from the time it is dispatched to a call.

CAD systems link the EMS system and its performance with operations research modeling efforts. As this section demonstrates, it is necessary to work closely with EMS personnel to determine how to interpret the data in the CAD system and to identify the most salient features in the EMS system. Moreover, evaluating EMS systems from the patient point of view is extremely challenging due to the lack of an accurate description of the patient experience.

McLay and Mayorga [19] use this data set to predict the expected additional number of lives lost if ambulances are located according to RTTs as opposed to patient survival rates. They evaluate the impact of T -minute RTTs, $T = 4, 5, \dots, 10$. Table 4 summarizes the expected number of lives lost over a 1-year period when seven ALS ambulances are located according to T -minute RTTs, $T = 4, 5, \dots, 10$, relative to the base case of 418 lives saved when ambulances are

Table 4. Expected Number of Lives Lost when Locating Seven Ambulances According to Response Time Thresholds

T -Minute RTT	Expected Number of Lives Lost	Ambulance Locations
4	1.49	1 , 1, 4, 6, 7, 7, 10
5	1.49	1 , 1, 4, 6, 7, 7, 10
6	0.81	1, 4, 6, 7, 7, 10, 14
7	0	1, 4, 6, 7, 7, 8, 10
8	0	1, 4, 6, 7, 7, 8, 10
9	2.10	1, 4, 6, 7, 8, 10, 14
10	2.10	1, 4, 6, 7, 8, 10, 14

optimally located according to patient survival. The resulting ambulance locations are listed as stations (refer to Fig. 2), with stations in bold in Table 4 denoting new stations used as compared to when ambulances are optimally located according to patient survival. Although the relative improvement in the number of lives saved is small (no more than 2.1 lives, on average), these lives could be saved at no additional cost, and it highlights the importance of appropriate performance measures in EMS system design and evaluation.

CONCLUSIONS

Operations research practitioners have the unique opportunity to make a difference in EMS system design. New directions in EMS systems need not merely be makeshift solutions for mending complex problems; they can be the result of modeling, analysis, and planning. This article summarizes how operations research can play a role in next-generation EMS system design that focuses on patient outcomes. Note that all EMS systems operate differently, and the issues raised in this article should be modified before being applied to other EMS systems.

Operations research has made an impact in EMS systems, particularly in the area of

locating medical units. There are many other areas within EMS system design and operation that could benefit from the application of operations research methodologies. The issues discussed represent but the tip of the iceberg. By using operations research methodologies to design and operate EMS systems, which save more patient lives, can drastically affect our nation's health and well-being.

Acknowledgments

It is a pleasure to acknowledge Dr. Joseph P. Ornato, M.D., Chair of the Department of Emergency Medicine at Virginia Commonwealth University and Medical Director for the Richmond Ambulance Authority, as well as Battalion Chief Henri Moore, Jr., Hanover Fire and EMS Chief Fred C. Crosby, II, Division Chief Eddie Buchanan, and Mr. Lawrence Roakes of the Hanover County Fire and EMS Department in Hanover County, Virginia, for the knowledge, experience, and data they provided to support this research effort as well as their feedback on a draft of this article. The data analysis was performed by Alisha Purohit for an Honors Summer Undergraduate Research Project program at Virginia Commonwealth University.

ESTIMATING FAILURE RATES AND HAZARD FUNCTIONS

MASSIMILIANO GIORGIO

Research Council (CNR),
Rome, Italy

The *failure rate* (or *hazard function*) $h(t)$ for a continuous lifetime distribution is defined as [1]:

$$\begin{aligned} h(t) &= \lim_{\Delta t \rightarrow 0} \frac{\Pr(t \leq T < t + \Delta t \mid T \geq t)}{\Delta t} \\ &= \frac{f(t)}{R(t)}, \quad t \geq 0, \end{aligned} \quad (1)$$

where $f(t)$ and $R(t)$ are the probability density function and the reliability function (also called *survival probability*), respectively, of the continuous nonnegative random variable T denoting the time-to-failure of a nonrepairable unit. The failure rate $h(t)$ specifies the instantaneous rate of failure at time t , given that the unit survives until t . Hence, the product $h(t) \cdot \Delta t$ is approximately the probability of failure in the time interval $[t, t + \Delta t)$, given survival till t . That is, in the short time Δt from t to $t + \Delta t$, a proportion $h(t) \cdot \Delta t$ of the population that reached age t is expected to fail [2]. Since $f(t) = -dR(t)/dt$, then $h(t) = -d \ln R(t)/dt$.

The *cumulative failure rate* (or *cumulative hazard function*) is defined as

$$H(t) = \int_0^t h(x) dx, \quad (2)$$

and is related to the reliability function $R(t)$ by the formula

$$H(t) = -\ln R(t). \quad (3)$$

It can be noted that, since $\lim_{t \rightarrow \infty} R(t) = 0$, the $\lim_{t \rightarrow \infty} H(t) = \infty$. Thus, the failure rate $h(t)$ for a continuous lifetime distribution possesses the properties

$$h(t) \geq 0 \quad \text{and} \quad \int_0^\infty h(x) dx = \infty.$$

In particular, note that being $\int_0^\infty h(x) dx = \infty$, $h(t)$ is not a probability function (i.e., only a pointwise probabilistic interpretation can be given for $h(t) \cdot \Delta t$) and no physical interpretation can be given to $H(t)$.

As the definition (Eq. 1) involves the concept of probability, the measurement of $h(t)$ and/or of $H(t)$ requires probabilistic and statistical methods. A number of classical nonparametric and parametric procedures for estimating the failure rate and the cumulative failure rate are illustrated here.

LIFETIME DATA COLLECTION

Any estimation procedure, or more generally, any method of lifetime data analysis, is strictly related to the way the data are collected. In particular, the exact value of the time-to-failure is only seldom known for all the units on test because to collect such a *complete* sample, it would be necessary to continuously monitor the units all along their life. On the contrary, very frequently, lifetime is known exactly only for a portion of the units on test, and incomplete information is available about the failure time of the other units (*censored* sample). Censoring arises in various ways and many different kinds of censored sampling are considered in literature [1,3,4]. The case of right censored observations is specifically addressed in the following section.

In general, a sample is called a *singly censored sample* if all the survivors have the same censoring time, whereas it is called a *multiply censored sample* if survivors have different censoring times. Random and staggered censorings usually give rise to multiply censored samples.

Only standard methods for censored data analysis are presented in this article. The use of these methods makes the assumption that censoring mechanisms are noninformative (or *independent*), that is, the probability of censoring at time t does not depend on the prognosis for failure at time t (i.e., the censoring time does not give information about the failure time distribution) [5].

NONPARAMETRIC PROCEDURES

Complete and Singly Right Censored Samples

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ denote a complete sample of n data from a single distribution function, and let $\mathbf{x} = \{x_{(1)}, \dots, x_{(s)}\}$ indicate the ordered set of the s distinct values of the set $\mathbf{t}$ ($s \leq n$). We have that $s < n$ in presence of ties. From the relationship (Eq. 3) between $H(t)$ and $R(t)$, a natural nonparametric estimator of the cumulative hazard function $H(t)$ at the time t is given by

$$\tilde{H}(t) = \begin{cases} 0, & \text{for } 0 \leq t < x_{(1)} \\ -\ln \left(1 - \sum_{j=1}^i \frac{d_j}{n} \right), & \text{for } x_{(i)} \leq t < x_{(i+1)}, \\ & i = 1, 2, \dots, s-1, \end{cases} \quad (4)$$

where $x_{(0)} \equiv 0$, d_j is the number of units failed at $x_{(j)}$ and $n - \sum_{j=1}^i d_j$ is the number of units which survive time $x_{(j)}$. $\tilde{H}(t)$ is a staircase function, that is it is flat between successive failure times. Of course, the true cumulative hazard function of a large population of identical units operating under identical working conditions should be regarded as a smooth curve. Thus, for applicative purpose, it can be useful to imagine the $H(t)$

function as a smooth, nondecreasing curve which passes through the plotted points $(x_{(i)}, \tilde{H}(x_{(i)}))$.

In the case of singly censored sample data, where all failure times are smaller than or equal to the unique single censoring time, say $T_C \geq x_{(s)}$, the same approach can be adopted

$$\tilde{H}(t) = \begin{cases} 0, & \text{for } 0 \leq t < x_{(1)} \\ -\ln \left(1 - \sum_{j=1}^i \frac{d_j}{n} \right), & \text{for } x_{(i)} \leq t < x_{(i+1)}, \\ & i = 1, 2, \dots, s-1, \\ -\ln \left(1 - \sum_{j=1}^s \frac{d_j}{n} \right), & \text{for } x_{(s)} \leq t \leq T_C \end{cases} \quad (5)$$

where $\sum_{j=1}^s d_j$ is the total number of failed items in the sample. Estimator 5 can also be used in the case of multiply censored samples if all failure times are not greater than the smallest censoring time. In this case, T_C equals the largest censoring time.

In the case of complete or singly censored samples, the exact $(1 - \alpha)$ confidence intervals for $H(t)$, say $(\tilde{H}_L(t), \tilde{H}_U(t))$, can be easily obtained from Ref. 6 as follows:

$$\begin{aligned} \tilde{H}_L(t) : & \sum_{j=0}^{n \exp[-\tilde{H}(t)]} \binom{n}{j} (\exp[-\tilde{H}_L(t)])^j \\ & \times (1 - \exp[-\tilde{H}_L(t)])^{n-j} = \alpha/2 \\ \tilde{H}_U(t) : & \sum_{j=0}^{n \exp[-\tilde{H}(t)]-1} \binom{n}{j} (\exp[-\tilde{H}_U(t)])^j \\ & \times (1 - \exp[-\tilde{H}_U(t)])^{n-j} = 1 - \alpha/2. \end{aligned} \quad (6)$$

Note that, thanks to the relationship between the cumulative binomial function and the cumulative beta distribution, the limits (Eq. 6) can be also obtained by inverting the cumulative beta distribution,

so that

$$\begin{aligned}\tilde{H}_L(t) &= -\ln \left(B_{1-\alpha/2}(n \exp\{-\tilde{H}(t)\} \right. \\ &\quad \left. + 1, n[1 - \exp\{-\tilde{H}(t)\}]) \right) \\ \tilde{H}_U(t) &= -\ln \left(B_{\alpha/2}(n \exp\{-\tilde{H}(t)\}, \right. \\ &\quad \left. n[1 - \exp\{-\tilde{H}(t)\} + 1]) \right), \quad (7)\end{aligned}$$

where $B_\gamma(p, q)$ denotes the γ th quantile of the beta distribution with parameters p and q . Of course, in case of censoring, the time axis can be investigated up to the censoring time, say $x_{(s)}$ or T_C . An approximate $(1 - \alpha)$ confidence interval for $H(t)$ can be obtained by using the normal approximation for the distribution of $\tilde{H}(t)$,

$$\begin{aligned}\tilde{H}_L(t) &= \tilde{H}(t) + z_{\alpha/2} \cdot \tilde{\sigma}_{\tilde{H}} \quad \text{and} \\ \tilde{H}_U(t) &= \tilde{H}(t) - z_{\alpha/2} \cdot \tilde{\sigma}_{\tilde{H}}, \quad (8)\end{aligned}$$

where $z_{\alpha/2}$ is the $\alpha/2$ th quantile of the standard normal distribution, and

$$\tilde{\sigma}_{\tilde{H}} = \sqrt{\frac{\exp[\tilde{H}(t)] - 1}{n}} \quad (9)$$

is an estimate of the standard deviation of $\tilde{H}(t)$. The normal approximation works well for large samples but, for small and moderate samples, Equation (8) can provide a negative lower confidence limit, so that $\tilde{H}_L(t) = 0$ must be adopted. A way to overcome such a problem is to assume a lognormal approximation for $\tilde{H}(t)$, so that an approximate $(1 - \alpha)$ confidence interval for $H(t)$ results in

$$\begin{aligned}\tilde{H}_L(t) &= \tilde{H} \cdot \exp(z_{\alpha/2} \tilde{\sigma}_{\tilde{H}} / \tilde{H}) \quad \text{and} \\ \tilde{H}_U(t) &= \tilde{H} \cdot \exp(-z_{\alpha/2} \tilde{\sigma}_{\tilde{H}} / \tilde{H}). \quad (10)\end{aligned}$$

All the illustrated procedures for constructing confidence intervals for $H(t)$ can be used also in the case of multiple censored samples, provided that censoring times are equal to or greater than the largest failure time. In this case, the time axis can be investigated until the largest censoring time.

An estimate of the failure rate $h(t)$ at any time $t \leq x_{(s)}$ (or $t \leq T_C$) can be obtained by

smoothing the increments of the estimator (Eq. 4 or 5) of the cumulative failure rate from time $x_{(i-1)}$ up to time $x_{(i)}$ ($i = 1, 2, \dots, s$), say $\Delta \tilde{H}_i = \tilde{H}(x_{(i)}) - \tilde{H}(x_{(i-1)})$, as given by the following expression from Ref. 7:

$$\tilde{h}_k(t) = \frac{1}{b_n} \sum_{i=1}^s W\left(\frac{t - x_{(i)}}{b_n}\right) \cdot \Delta \tilde{H}_i, \quad (11)$$

where

$$\Delta \tilde{H}_i = \ln \frac{n - \sum_{j=1}^{i-1} d_j}{n - \sum_{j=1}^i d_j}, \quad i = 1, 2, \dots, s, \quad (12)$$

b_n is a sequence of smoothing parameters, known as the *bandwidth*, satisfying $b_n \rightarrow 0$ but $n b_n \rightarrow \infty$ as the sample size n tends to infinity, and the *kernel function* $W(z)$ is a bounded nonnegative weight function which satisfies $\int_{-\infty}^{\infty} W(z) dz = 1$. The kernel $W(z)$ is typically assumed to be a symmetric probability density function with zero mean and unit variance. For example, $W(z)$ can be the normal density function. The level of smoothness is set by the bandwidth b_n : the larger the b_n , the smoother the $\tilde{h}_k(t)$. Note that two relevant problems occur when applying kernel estimators: the boundary effects near the endpoints of the support of the failure rate and a substantial increase in the variance from left to right over the range of abscissae where the failure rate is estimated. Boundary-corrected kernel estimators and practical bandwidth choices can be found in Ref. 8. Further details about kernel estimators may be found in Ref. 9.

Multiply Censored Samples with Intermixed Failure and Censoring Times

Multiply censored samples are usually characterized by the fact that failures and censoring times are intermixed. In this case, the nonparametric estimator (Eq. 5) cannot be used and *ad hoc* methods must be used.

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ denote a random sample of size n consisting of r failure times and $n - r$ censored observations, and let $\mathbf{x} = \{x_{(1)}, x_{(2)}, \dots, x_{(s)}\}$ denote the ordered set

of the s ($s \leq r$) distinct values of the set $\mathbf{t}$. Moreover, let d_i ($i = 1, 2, \dots, s$) denote the number of failures occurring at the same time $x_{(i)}$ ($\sum_{i=1}^s d_i = r$), let C_i denote the total number of censoring events that occurred before time $x_{(i)}$, and let k_i indicate the number of units at risk (neither failed nor withdrawn) immediately before $x_{(i)}$:

$$k_i = n - \sum_{j=1}^{i-1} d_j - C_i. \quad (13)$$

Due to Equation (3), a Kaplan–Meier (KM)-based estimate of $H(t)$ is as follows from Ref. 2:

$$\begin{aligned} \bar{H}(t) &= \begin{cases} 0, & 0 \leq t < x_{(1)} \\ -\sum_{j=1}^i \ln \left(1 - \frac{d_j}{k_j} \right), & x_{(i)} \leq t < x_{(i+1)}, \\ & i = 1, 2, \dots, s-1, \\ -\sum_{j=1}^s \ln \left(1 - \frac{d_j}{k_j} \right), & x_{(s)} \leq t \leq t_{\max} \end{cases} \end{aligned} \quad (14)$$

and $t_{\max}$ is the largest value in $\{t_1, t_2, \dots, t_n\}$. Note that, in case of a tie between a censoring time and the generic failure time $x_{(i)}$, the KM method assumes that the censoring time is infinitesimally larger than the failure time, so that the censored unit is still at risk at $x_{(i)}$.

The standard deviation $\sigma_{\bar{H}}$ of $\bar{H}(t)$, based on the Greenwood formula [1], may be obtained as follows:

$$\sigma_{\bar{H}} = \sqrt{\sum_{j: x_{(j)} \leq t} \frac{d_j}{k_j(k_j - d_j)}}. \quad (15)$$

An alternative to the KM-based estimator (Eq. 14) is the Nelson–Aalen (NA) estimator [1]:

$$\hat{H}(t) = \sum_{j: x_{(j)} \leq t} \frac{d_j}{k_j}. \quad (16)$$

For continuous models, $\bar{H}(t)$ and $\hat{H}(t)$ are asymptotically (i.e., for large n) equivalent

and do not differ greatly in most situations, except for large t values. In fact,

$$\begin{aligned} \bar{H}(t) &= - \sum_{j: x_{(j)} < t} \ln \left(1 - \frac{d_j}{k_j} \right) \\ &= \sum_{j: x_{(j)} < t} \left(\frac{d_j}{k_j} + \frac{d_j^2}{2k_j^2} + \dots \right) \end{aligned} \quad (17)$$

and thus, $\hat{H}(t)$ is a first-order approximation to $\bar{H}(t)$ [1]. This asymptotic equivalence makes it possible for the standard deviation $\sigma_{\hat{H}}$ of $\hat{H}(t)$ to be estimated from Equation (15).

Approximate confidence intervals for $H(t)$, at any fixed time $t \leq t_{\max}$, can be obtained through the normal or the lognormal approximation for the distribution of the estimator, using $\bar{H}(t)$ or $\hat{H}(t)$ in place of $\tilde{H}(t)$ in Equation (8) or (10), and estimating the standard deviation through Equation (15).

A kernel smoothing of the estimated increments $\Delta \bar{H}_i = \bar{H}(x_{(i)}) - \bar{H}(x_{(i-1)}) = \ln(1 - d_i/k_i)$ and $\Delta \hat{H}_i = \hat{H}(x_{(i)}) - \hat{H}(x_{(i-1)}) = d_i/k_i$ ($i = 1, 2, \dots, s$) of the cumulative failure rate from time $x_{(i-1)}$ up to time $x_{(i)}$, provides smooth estimates of the failure rate $h(t)$ at any time $t \leq t_{\max}$, as given by Ref. 7:

$$\begin{aligned} \bar{h}_k(t) &= \frac{1}{b_n} \sum_{i=1}^s W \left(\frac{t - x_{(i)}}{b_n} \right) \cdot \Delta \bar{H}_i \quad \text{and} \\ \hat{h}_k(t) &= \frac{1}{b_n} \sum_{i=1}^s W \left(\frac{t - x_{(i)}}{b_n} \right) \cdot \Delta \hat{H}_i. \end{aligned} \quad (18)$$

Example 1. Let us consider the data on field windings of $n = 16$ generators given by Nelson [2]. These data consist of $r = 7$ failure times (in months) of the failed windings and of $n - r = 9$ running times (in months) of the windings that did not fail (Table 1, where the asterisk denotes censoring times). The failure and censored times are intermixed because the units were put into service at different times. The largest time is a censoring time, equal to $t_{\max} = 130$ months, and there are no tied failure times, so that $s = r = 7$ and $d_i = 1$ for any failure time.

Table 1. The Winding Data in Example 1

i	t_i (mo)	i	t_i (mo)
1	31.7	9	87.5 ^a
2	39.2	10	88.3 ^a
3	57.5	11	94.2 ^a
4	65.0 ^a	12	101.7 ^a
5	65.8	13	105.8
6	70.0	14	109.2 ^a
7	75.0 ^a	15	110
8	75.0 ^a	16	130 ^a

^aDenotes a censoring time.

The distinct ordered times $x_{(i)}$ ($i = 1, 2, \dots, 7$) at which failures occurred, the total number C_i of windings censored before $x_{(i)}$, and the number k_i of windings at risk immediately before $x_{(i)}$, computed through Equation (13), are given in Table 2.

The cumulative hazard function $H(t)$ is estimated through the NA estimator (Eq. 16) and its standard deviation $\sigma_{\hat{H}}$ is estimated from Equation (15). Table 2 gives both $H(t)$ and $\hat{\sigma}_{\hat{H}}$ at each failure time $x_{(i)}$ ($i = 1, 2, \dots, 7$), together with the approximate 90% confidence intervals obtained from both, Equation (8) [i.e., based on the normal approximation for $\hat{H}(t)$] and from Equation (10) (i.e., based on the lognormal approximation). As expected, due to the small size of the sample, the lower confidence limits provided by Equation (8) are negative for some times t , and then for such times $\hat{H}_L(t) = 0$ should be adopted. For a comparative purpose, the last column of Table 2 gives the KM-based estimator $\bar{H}(t)$ too. As expected, the two estimates $H(t)$ and $\bar{H}(t)$ are quite close to each other, except for t values larger than 100 months when $\bar{H}(t)$ exceeds $\hat{H}(t)$ sensibly.

Figure 1 depicts the kernel estimates $\hat{h}_k(t)$ obtained for $b_n = 5$ and 10 months, and using a normal density function as kernel function $W(z)$. The kernel estimates give evidence of increasing failure rate with age t and, as expected, the larger value of the bandwidth b_n provides the smoother function.

For large samples, a suitable alternative to the estimates (Eqs 14 and 16) is available if the whole time interval $(0, t_{\max})$ is partitioned into a number m of subintervals, say $(\tau_{i-1}, \tau_i]$ ($i = 1, 2, \dots, m$), being $\tau_0 \equiv 0$ and

$\tau_m = t_{\max}$, and both failure and censoring data are grouped into the m subintervals. These subintervals may be of equal length, but this is not necessary; they only have to be contiguous. In this case, the actuarial-based estimator $\tilde{H}_A(\tau_i)$ of $H(\tau_i)$ [2] is

$$\tilde{H}_A(\tau_i) = - \sum_{j=1}^i \ln \left(1 - \frac{d_j}{k_j - c_j/2} \right),$$

where $i = 1, 2, \dots, m$, (19)

and k_i, c_i , and d_i , are the respective number of units at risk at the beginning of the i th subinterval $(\tau_{i-1}, \tau_i]$, the number of units withdrawn from the test during $(\tau_{i-1}, \tau_i]$, and the number of failures occurred in $(\tau_{i-1}, \tau_i]$. Of course, $k_1 = n$ and $k_{i+1} = k_i - d_i - c_i$ ($i = 1, 2, \dots, m-1$). The factor $-c_j/2$ adjusts for the censored units, which are assumed to run about half the j th subinterval. Other censoring adjustments have been proposed in the literature [10].

In contrast to the KM-based estimator (Eq. 14) and to the NA estimator (Eq. 16), the actuarial-based estimator (Eq. 19) gives estimates at the endpoints of the subintervals. If the i th subinterval contains one or more failures, then $\tilde{H}_A(t)$ is to be considered undefined within this subinterval. If zero failure occur in (τ_{i-1}, τ_i) , then $\tilde{H}_A(t) = \tilde{H}_A(\tau_{i-1})$ for any $\tau_{i-1} \leq t < \tau_i$.

Approximate confidence intervals for $H(t)$ can be obtained by assuming the lognormal distribution for $\tilde{H}_A(t)$ (Eq. 10), where the approximate standard deviation of $\tilde{H}_A(t)$ is estimated from the Greenwood formula (Eq. 16), taking into account that, approximately, $\tilde{\sigma}_{\tilde{H}} \cong \tilde{\sigma}_{\tilde{R}}/\tilde{R}(t)$ and using the adjusted $k_j - c_j/2$ instead of k_j :

$$\tilde{\sigma}_{\tilde{H}_A} = \sqrt{\sum_{j=1}^i \frac{d_j}{(k_j - c_j/2) \cdot (k_j - c_j/2 - d_j)}}. \quad (20)$$

When data are grouped, a nonparametric estimate of the failure rate $h(t)$ can be obtained from a combination of smoothing central rates of failures and a suitable transformation of the central failure rate, where

Table 2. Winding Failure Times, NA Estimate $\hat{H}(t)$, Estimated Standard Deviation $\hat{\sigma}_{\hat{H}}$, 95% Approximate Confidence Intervals Based on the Normal and Lognormal Approximation, and Kaplan–Meier-based (KM) Estimate $\bar{H}(t)$ in Example 1

Figure 1. Plot of the kernel estimates of $h(t)$ for the data in Example 1.

the central failure rate for the i th subinterval is defined as follows from Ref. 11:

$$\tilde{h}_{c_i} = \frac{2d_i}{(k_i + k_{i+1})(\tau_i - \tau_{i-1})}, \quad i = 1, 2, \dots, m, \quad (21)$$

where $k_{m+1} = k_m - d_m - c_m$ is the number of units at risk at $t_{\max}$. Then, the smoothed central failure rate is obtained by smoothing the points $(\tau_i + \tau_{i-1})/2, \tilde{h}_{c_i}$ ($i = 1, 2, \dots, m$), for example with weighted least-squares smoothers or with spline smoothers, and a recommended transformation is discussed in Ref. 12.

PARAMETRIC PROCEDURES

Parametric estimation procedures require that a probability model is assumed for the failure time distribution, say

$$T \sim f(t; \boldsymbol{\theta}), \quad t \geq 0, \quad (22)$$

where $\boldsymbol{\theta} = \{\theta_1, \theta_2, \dots, \theta_l\}$ is the vector of l parameters, some of which are unknown. Among all the parametric estimation procedures, only the maximum likelihood (ML) estimation method is discussed here, and the specific cases of the standard exponential and two-parameter Weibull distributions are considered in detail.

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ denote a random sample of size n of exact failure times and right censored data from the failure time distribution $f(t; \boldsymbol{\theta})$. The idea behind ML estimation is that the value of model parameters which maximizes the probability (likelihood) of the sample data is their best estimate. In this context, the (joint) data probability function is called the *likelihood function*, say $L(\boldsymbol{\theta}; \mathbf{t})$, to highlight that it is regarded as a

function of the unknown parameters. Since multiplying the joint distribution function by a constant does not alter the ML estimates, the likelihood function is usually defined up to a *constant* multiplicative factor (where the term *constant* means that it does not depend on the unknown parameters, even if it may possibly depend on the data). Under such hypotheses, the likelihood function $L(\theta; \mathbf{t})$ can be formulated as follows:

$$L(\theta; \mathbf{t}) = \prod_{i=1}^n f(t_i; \theta)^{\delta_i} \cdot R(t_i; \theta)^{1-\delta_i}, \quad (23)$$

where $\delta_i = 1$ if t_i is an exact failure time, and $\delta_i = 0$ if t_i is a right censored observation.

The ML estimate of θ , say $\hat{\theta} = \{\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_l\}$, can be obtained (if it exists) as:

$$\hat{\theta} = \max_{\theta \in \Theta} L(\theta; \mathbf{t}), \quad (24)$$

with Θ being the space of the parameters. Hence, the ML estimate of the failure rate, say $\hat{h}(t)$, and of the cumulative failure rate, say $\hat{H}(t)$, for any time $t \geq 0$ can be easily obtained for any time t as

$$\hat{h}(t) = h(t; \hat{\theta}) \quad \text{and} \quad \hat{H}(t) = H(t; \hat{\theta}). \quad (25)$$

If an analytic closed-form expression exists for $h(t)$, the distribution function can be re-parameterized so that the value of the failure rate at whatever prefixed time x , say $h(x)$, explicitly appears as a parameter of the probability model. In this case, a direct estimation of $h(x)$ can be performed and the direct estimate, due to the invariance property of the ML method, will coincide with the indirect estimate (Eq. 25). Of course, the same result holds for $H(t)$.

Instead of maximizing the likelihood function (Eq. 23), it is generally much more convenient to maximize the log-likelihood function:

$$\begin{aligned} \ell(\theta; \mathbf{t}) &= \ln L(\theta; \mathbf{t}) \\ &= \sum_{i=1}^n \delta_i \cdot \ln f(t_i; \theta) + (1 - \delta_i) \cdot \ln R(t_i; \theta). \end{aligned} \quad (26)$$

In fact, the logarithm function is a monotone increasing function, and thus the

value $\hat{\theta}$ that maximizes $\ell(\theta; \mathbf{t})$, if it exists, is the same as the one that maximizes $L(\theta; \mathbf{t})$. The advantage in maximizing the log-likelihood function is that a logarithmic transformation usually yields simplified mathematics, since it transforms products in sums and often prevents such computational problems as overflows and/or underflows, often caused by Equation (23).

Approximate confidence intervals for $h(t)$ and $H(t)$, homolog to the confidence intervals for nonparametric estimates, can be obtained adopting the normal approximation for the distribution of $\hat{h}(t)$ and $\hat{H}(t)$, respectively, so that

$$\begin{aligned} (\hat{h}_L(t), \hat{h}_U(t)) &= \left(\hat{h}(t) + z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{h}(t))}, \right. \\ &\quad \left. \hat{h}(t) - z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{h}(t))} \right), \end{aligned} \quad (27)$$

$$\begin{aligned} (\hat{H}_L(t), \hat{H}_U(t)) &= \left(\hat{H}(t) + z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{H}(t))}, \right. \\ &\quad \left. \hat{H}(t) - z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{H}(t))} \right), \end{aligned} \quad (28)$$

where $z_{\alpha/2}$ is the $\alpha/2$ th quantile of the standard normal distribution, and $\hat{\text{Var}}(\hat{h}(t))$ and $\hat{\text{Var}}(\hat{H}(t))$ denote the estimates of the asymptotic variance of $\hat{h}(t)$ and $\hat{H}(t)$, respectively. Such variances can be obtained through the delta method [13]:

$$\begin{aligned} \hat{\text{Var}}(\hat{h}(t)) &= \sum_{i=1}^l \left[\frac{\partial h(t)}{\partial \theta_i} \Big|_{\hat{\theta}} \right]^2 \cdot \hat{\text{Var}}(\hat{\theta}_i) \\ &\quad + 2 \cdot \sum_{i=1}^l \sum_{j=i+1}^l \frac{\partial h(t)}{\partial \theta_i} \Big|_{\hat{\theta}} \frac{\partial h(t)}{\partial \theta_j} \Big|_{\hat{\theta}} \\ &\quad \cdot \hat{\text{Cov}}(\hat{\theta}_i, \hat{\theta}_j), \end{aligned} \quad (29)$$

$$\begin{aligned} \hat{\text{Var}}(\hat{H}(t)) &= \sum_{i=1}^l \left[\frac{\partial H(t)}{\partial \theta_i} \Big|_{\hat{\theta}} \right]^2 \cdot \hat{\text{Var}}(\hat{\theta}_i) \\ &\quad + 2 \cdot \sum_{i=1}^l \sum_{j=i+1}^l \frac{\partial H(t)}{\partial \theta_i} \Big|_{\hat{\theta}} \frac{\partial H(t)}{\partial \theta_j} \Big|_{\hat{\theta}} \\ &\quad \cdot \hat{\text{Cov}}(\hat{\theta}_i, \hat{\theta}_j), \end{aligned} \quad (30)$$

where $\hat{\text{Var}}(\hat{\theta}_i)$ and $\hat{\text{Cov}}(\hat{\theta}_i, \hat{\theta}_j)$ ($i, j = 1, \dots, l$) are the elements (i, i) and (i, j) respectively, of the estimated $l \times l$ asymptotic variance–covariance matrix $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ of the parameter vector $\boldsymbol{\theta}$ (refer Appendix) and the partial derivatives of $h(t)$ and $H(t)$ with respect to the model parameters must be evaluated at the ML estimate $\hat{\boldsymbol{\theta}}$.

As an alternative, confidence limits can be based on the lognormal approximation for the distribution of $\hat{h}(t)$ and $\hat{H}(t)$, so that

$$\begin{aligned} &(\hat{h}_L(t), \hat{h}_U(t)) \\ &= \left(\hat{h}(t) \cdot \exp \left[z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{h}(t))/\hat{h}(t)} \right], \right. \\ &\quad \left. \hat{h}(t) \cdot \exp \left[-z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{h}(t))/\hat{h}(t)} \right] \right), \end{aligned} \quad (31)$$

$$\begin{aligned} &(\hat{H}_L(t), \hat{H}_U(t)) \\ &= \left(\hat{H}(t) \cdot \exp \left[z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{H}(t))/\hat{H}(t)} \right], \right. \\ &\quad \left. \hat{H}(t) \cdot \exp \left[-z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{H}(t))/\hat{H}(t)} \right] \right), \end{aligned} \quad (32)$$

which, unlike Equations (27) and (28), ensures that the lower limits are always positive for any $t > 0$, even for small samples.

If the probability density function can be re-parameterized in terms of the failure rate $h(x)$ evaluated at a specific time x of interest and in terms of $(l - 1)$ remaining parameters, say $\{\theta_1, \dots, \theta_{k-1}, \theta_{k+1}, \dots, \theta_l\}$, then $h(x)$ becomes one of the model parameters, say $h(x) \equiv \theta_k$, and the estimated variance of $\hat{h}(x)$ is just the element (k, k) of the matrix $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$. Clearly, the same result holds for $H(x)$.

Also the approximate confidence intervals (Eqs 31 and 32) generally work badly if the sample size is small. More accurate approximation can be obtained by using the parametric bootstrap procedure, which consists of choosing a suitable model for the observed data, estimating the model parameters (often by the ML method) and the quantity of interest, say $h(x)$, from the observed data, resampling from this (estimated) parametric model, and finally estimating $h(x)$ from the bootstrap sample [14]. If the resampling procedure

is repeated a large number of times, the empirical distribution of the bootstrap estimates, say $\{\hat{h}^{(1)}, \hat{h}^{(2)}, \hat{h}^{(3)}, \dots\}$, serves as an approximation to the sampling distribution of $\hat{h}(x)$, and an approximate confidence interval for $h(x)$ can be obtained.

Exact solutions for the interval estimation problem are sometimes available, depending on the lifetime distribution model and the censoring scheme. In the following, some procedures (both exact and approximate) for the one-parameter (or standard) exponential and two-parameter Weibull distributions are presented.

Data from the One-Parameter Exponential Distribution

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ denote a random sample of size n consisting of r failure times and $n - r$ censored observations from a one-parameter exponential random variable with density function:

$$f(t; \lambda) = \lambda \exp(-\lambda \cdot t); \quad \lambda > 0, t \geq 0, \quad (33)$$

where the parameter λ is just the constant failure rate. The reliability function is

$$R(t; \lambda) = \exp(-\lambda \cdot t); \quad \lambda > 0, t \geq 0. \quad (34)$$

The likelihood function $L(\lambda; \mathbf{t})$ results in

$$\begin{aligned} L(\lambda; \mathbf{t}) &\propto \prod_{i=1}^n \lambda^{\delta_i} \exp(-\lambda \cdot \delta_i \cdot t_i) \\ &\quad \cdot \exp[-\lambda \cdot (1 - \delta_i) \cdot t_i] = \\ &= \prod_{i=1}^n \lambda^{\delta_i} \exp(-\lambda \cdot t_i) \\ &= \lambda^r \cdot \exp \left(-\lambda \cdot \sum_{i=1}^n t_i \right), \end{aligned} \quad (35)$$

where $\delta_i = 1$ if t_i is an exact failure time, and $\delta_i = 0$ if t_i is a right censored observation. Thus, $\sum_{i=1}^n \delta_i = r$ is the number of exact failure times and the sum $\sum_{i=1}^n t_i$ is the total time on test. The log-likelihood function $\ell(\lambda; \mathbf{t})$ is

$$\ell(\lambda; \mathbf{t}) = \ln \left[\lambda^r \exp \left(-\lambda \cdot \sum_{i=1}^n t_i \right) \right]$$

$$= r \ln \lambda - \lambda \sum_{i=1}^n t_i, \quad (36)$$

and for $r > 0$, the ML estimate of the failure rate λ is equal to the number of observed failures over the total time on test [1]:

$$\hat{\lambda} = \frac{r}{\sum_{i=1}^n t_i}. \quad (37)$$

The ML estimate of cumulative failure rate $H(t)$ can be straightforwardly obtained as

$$\hat{H}(t) = \int_0^t \hat{h}(x) dx = \hat{\lambda} t. \quad (38)$$

In the case of complete or Type II censored sample, the exact $(1 - \alpha)$ confidence interval for the failure rate λ is given by the following expression [15]:

$$\begin{aligned} (\hat{\lambda}_L, \hat{\lambda}_U) &= \left(\frac{\hat{\lambda} \chi_{\alpha/2}^2(2r)}{2r}, \frac{\hat{\lambda} \chi_{1-\alpha/2}^2(2r)}{2r} \right) \\ &= \left(\frac{\chi_{\alpha/2}^2(2r)}{2 \cdot \sum_{i=1}^n t_i}, \frac{\chi_{1-\alpha/2}^2(2r)}{2 \cdot \sum_{i=1}^n t_i} \right), \end{aligned} \quad (39)$$

where $\chi_{\gamma}^2(\nu)$ is the γ th quantile of the χ -square distribution with ν degrees of freedom. Since $H(t) = \lambda t$ for any fixed $t > 0$, the exact $(1 - \alpha)$ confidence interval for $H(t)$ is

$$\begin{aligned} (\hat{H}_L(t), \hat{H}_U(t)) &= (\hat{\lambda}_L t, \hat{\lambda}_U t) \\ &= \left(\frac{t \cdot \chi_{\alpha/2}^2(2r)}{2 \cdot \sum_{i=1}^n t_i}, \frac{t \cdot \chi_{1-\alpha/2}^2(2r)}{2 \cdot \sum_{i=1}^n t_i} \right). \end{aligned} \quad (40)$$

In the case of singly Type I censored sample or multiply censored sample, exact confidence intervals for λ , and hence for $H(t)$, are not available [16]. An approximate $(1 - \alpha)$ confidence interval for λ can

be obtained by employing the asymptotic normal approximation of $(\hat{\lambda} - \lambda)/\hat{\sigma}_{\hat{\lambda}}$, where $\hat{\sigma}_{\hat{\lambda}} = \hat{\lambda}/\sqrt{r}$ is the estimated asymptotic standard deviation of $\hat{\lambda}$ (obtained by inverting the estimated 1×1 information matrix $\hat{\mathbf{J}}(\hat{\theta})$, refer Appendix). Under such an approximation, we have from Ref. 1,

$$(\hat{\lambda}_L, \hat{\lambda}_U) = (\hat{\lambda} + z_{\alpha/2} \hat{\lambda}/\sqrt{r}, \hat{\lambda} - z_{\alpha/2} \hat{\lambda}/\sqrt{r}). \quad (41)$$

This approximation works well for moderate and large samples, whereas for small samples a better approximation [17] is given by

$$\begin{aligned} (\hat{\lambda}_L, \hat{\lambda}_U) &= \left(\left[\hat{\lambda}^{1/3} + z_{\alpha/2} \frac{\hat{\lambda}^{1/3}}{3\sqrt{r}} \right]^3, \right. \\ &\quad \left. \left[\hat{\lambda}^{1/3} - z_{\alpha/2} \frac{\hat{\lambda}^{1/3}}{3\sqrt{r}} \right]^3 \right), \end{aligned} \quad (42)$$

which employs the normal approximation of $\hat{\lambda}^{1/3}$ in small samples. Another approximate method (often attributed to Ref. 18), which works well in the case of singly Type I censored samples, treats $2r\lambda/\hat{\lambda}$ as being approximately distributed as a χ -square random variable with $(2r + 1)$ degrees of freedom, so that

$$(\hat{\lambda}_L, \hat{\lambda}_U) = \left(\frac{\hat{\lambda} \chi_{\alpha/2}^2(2r + 1)}{2r}, \frac{\hat{\lambda} \chi_{1-\alpha/2}^2(2r + 1)}{2r} \right). \quad (43)$$

Whichever asymptotic approximation is used to compute confidence limits for λ , an approximate $(1 - \alpha)$ confidence interval for $H(t)$ is given by

$$(\hat{H}_L(t), \hat{H}_U(t)) = (\hat{\lambda}_L t, \hat{\lambda}_U t). \quad (44)$$

Example 2. Let us consider the Type I censored data given in Ref. 19 which refers to 15 units of an electromechanical module tested at the temperature of 125°C. All the tests were stopped at the time $T_C = 1100$ h and 8 failures were observed at no tied times

$x_{(i)}$ ($i = 1, 2, \dots, 8$):

$$x_{(1)} = 88 \text{ h}, x_{(2)} = 105 \text{ h}, x_{(3)} = 141 \text{ h},$$

$$x_{(4)} = 344 \text{ h}, x_{(5)} = 430 \text{ h}, x_{(6)} = 516 \text{ h},$$

$$x_{(7)} = 937 \text{ h}, x_{(8)} = 1057 \text{ h}.$$

By assuming that the data follow the one-parameter exponential function, the ML estimate of the failure rate is

$$(\hat{\lambda}_L, \hat{\lambda}_U) = \begin{cases} (0.000217 \text{ h}^{-1}, 0.001197 \text{ h}^{-1}), & \text{from the normal approximation of } \hat{\lambda} \\ (0.000321 \text{ h}^{-1}, 0.001318 \text{ h}^{-1}), & \text{from the normal approximation of } \hat{\lambda}^{1/3} \\ (0.000334 \text{ h}^{-1}, 0.001334 \text{ h}^{-1}), & \text{from the } \chi^2 \text{-square approximation of } 2r\lambda/\hat{\lambda}, \end{cases} \quad (46)$$

being $\hat{\sigma}_{\hat{\lambda}} = \hat{\lambda}/\sqrt{r} = 0.000250 \text{ h}^{-1}$, $z_{0.025} = -1.960$, $\chi_{0.025}^2(17) = 7.564$, and $\chi_{0.975}^2(17) = 30.191$. From Equation (46), by using Equation (44), approximate 95% confidence

$$\hat{\lambda} = r / \sum_{i=1}^n t_i = 0.000707 \text{ h}^{-1}, \quad (45)$$

with r being the number of exact failure times equal to 8 and the total time on test $\sum_{i=1}^{15} t_i = 11,318 \text{ h}$. From Equations (41), (42) and (43), approximate 95% confidence intervals for λ are

intervals for $H(t)$ can be easily obtained for any t value of interest. For example, for $t = 500 \text{ h}$:

$$(\hat{H}_L(500), \hat{H}_U(500)) = \begin{cases} (0.109, 0.598), & \text{from the normal approximation of } \hat{\lambda} \\ (0.161, 0.659), & \text{from the normal approximation of } \hat{\lambda}^{1/3} \\ (0.167, 0.667), & \text{from the } \chi^2 \text{-square approximation of } 2r\lambda/\hat{\lambda}. \end{cases} \quad (47)$$

Since the size of the sample is not large, the confidence intervals based on the normal approximation of $\hat{\lambda}$ should be discarded. The remaining two approximations should both, work better and give confidence intervals close to each other.

Data from the Two-Parameter Weibull Distribution

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ be a random sample of size n consisting of r failure times and $n - r$ censored observations from a two-parameter Weibull random variable with density function

$$f(t; \theta, \beta) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1} \exp \left[- \left(\frac{t}{\theta} \right)^{\beta} \right], \quad \theta, \beta > 0, t \geq 0 \quad (48)$$

and reliability function

$$R(t; \theta, \beta) = \exp \left[- \left(\frac{t}{\theta} \right)^{\beta} \right], \quad \theta, \beta > 0, t \geq 0. \quad (49)$$

The likelihood function $L(\alpha, \beta; \mathbf{t})$ is

$$\begin{aligned} L(\theta, \beta; \mathbf{t}) &\propto \prod_{i=1}^n \left(\frac{\beta}{\theta} \right)^{\delta_i} \left(\frac{t_i}{\theta} \right)^{\delta_i(\beta-1)} \\ &\times \exp \left[-\delta_i \left(\frac{t_i}{\theta} \right)^{\beta} \right] \exp \left[-(1 - \delta_i) \cdot \left(\frac{t_i}{\theta} \right)^{\beta} \right] \\ &= \frac{\beta^r}{\theta^{r\beta}} \left(\prod_{i=1}^n t_i^{\delta_i} \right)^{\beta-1} \exp \left[- \left(\frac{\sum_{i=1}^n t_i^{\beta}}{\theta^{\beta}} \right) \right], \end{aligned} \quad (50)$$

where $\sum_{i=1}^n \delta_i = r$ is the number of exact failure times. The log-likelihood function $\ell(\theta, \beta; \mathbf{t})$ results in

$$\begin{aligned} \ell(\theta, \beta; \mathbf{t}) &= r \ln \beta - r \beta \ln \theta \\ &+ (\beta - 1) \cdot \sum_{i=1}^n (\delta_i \ln t_i) - \left(\frac{\sum_{i=1}^n t_i^{\beta}}{\theta^{\beta}} \right). \end{aligned} \quad (51)$$

By maximizing Equation (51), the ML estimate of the scale parameter θ is given by

$$\hat{\theta} = \left(\frac{\sum_{i=1}^n t_i^{\hat{\beta}}}{r} \right)^{1/\hat{\beta}}, \quad (52)$$

where the ML estimate $\hat{\beta}$ of the shape parameter β is the solution of

$$\frac{1}{\hat{\beta}} + \frac{\sum_{i=1}^n \delta_i \cdot \ln t_i}{r} - \frac{\sum_{i=1}^n t_i^{\hat{\beta}} \cdot \ln t_i}{\sum_{i=1}^n t_i^{\hat{\beta}}} = 0. \quad (53)$$

From definitions (Eqs 1 and 2), the failure rate and the cumulative failure rate for a two-parameter Weibull random variable are

$$h(t; \theta, \beta) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1} \text{ and} \\ H(t; \theta, \beta) = \left(\frac{t}{\theta} \right)^{\beta} \quad (54)$$

respectively, and their ML estimates at a given time t ($t \geq 0$) are

$$\hat{h}(t) = \frac{\hat{\beta}}{\hat{\theta}} \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}-1} \text{ and } \hat{H}(t) = \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}}. \quad (55)$$

The ML estimate of the cumulative failure rate at a given time x ($x > 0$) of interest, say $H_x \equiv H(x)$, can also be obtained directly re-parameterizing the log-likelihood function in terms of H_x and β . In this case, being $\theta = x/H_x^{1/\beta}$, the re-parameterized density and reliability functions result in

$$f(t; H_x, \beta) = \frac{\beta}{x} \left(\frac{t}{x} \right)^{\beta-1} \\ \times H_x \cdot \exp \left[-H_x \cdot \left(\frac{t}{x} \right)^{\beta} \right], \\ H_x > 0, \beta > 0, t \geq 0, \quad (56)$$

$$R(t; H_x, \beta) = \exp \left[-H_x \cdot \left(\frac{t}{x} \right)^{\beta} \right], \\ H_x > 0, \beta > 0, t \geq 0. \quad (57)$$

Expressions from Equations (56) and (57) can then be used to obtain the re-parameterized log-likelihood function $\ell(H_x, \beta; \mathbf{t})$. Maximizing $\ell(H_x, \beta; \mathbf{t})$ with respect to H_x and β gives the same ML estimates $\hat{H}_x = \hat{H}(x)$ and $\hat{\beta}$ as those obtained, via Equation (55), by maximizing the log-likelihood (Eq. 51). A similar procedure is to be used if we want to estimate directly the failure rate $h_x \equiv h(x)$ at a given time x , being $\theta = [\beta x^{\beta-1}/H_x]^{1/\beta}$.

In the case of complete samples, exploiting the fact that the distribution of $\hat{R}(t)$ depends only on $R(t)$ and n , the exact lower confidence limits for $R(t)$, say $\hat{R}_L(t)$, were obtained through a Monte Carlo simulation method and tabulated in Ref. 20. Then, from Equation (3), the exact upper confidence limit for $H(t)$ can be easily obtained:

$$\hat{H}_U(t) = -\ln [\hat{R}_L(t)]. \quad (58)$$

Alternatively, an iterative procedure given in Ref. 21 to compute $\hat{R}_L(t)$ allows $\hat{H}_U(t)$ to be obtained by using Equation (58). However, such a procedure is somewhat inconvenient, and the upper $(1 - \alpha)$ limit $\hat{H}_U(t)$ can be more easily computed by interpolating the $(1 - \alpha)$ lower confidence limits for $R(t)$ given in Table 7A of Ref. 21, for n ranging from 8 up to 100, $\hat{R}(t) = 0.50(0.02)0.98$, $\alpha = 0.25, 0.15, 0.10, 0.05$, and 0.02 .

For large samples, under the normal approximation for the distribution of $\hat{h}(t)$ and $\hat{H}(t)$, simple approximate $(1 - \alpha)$ confidence intervals for $h(t)$ and $H(t)$ can be obtained from Equations (27) and (28), respectively. The asymptotic variances $\hat{\text{Var}}(\hat{h}(t))$ and $\hat{\text{Var}}(\hat{H}(t))$ can be estimated through the delta method:

$$\hat{\text{Var}}(\hat{h}(t)) = \left[\frac{\partial h(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \right]^2 \cdot \hat{\text{Var}}(\hat{\theta}) \\ + \left[\frac{\partial h(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \right]^2 \cdot \hat{\text{Var}}(\hat{\beta})$$

$$\begin{aligned}
& + 2 \cdot \frac{\partial h(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \cdot \frac{\partial h(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \\
& \cdot \hat{\text{Cov}}(\hat{\theta}, \hat{\beta}), \quad (59) \\
\hat{\text{Var}}(\hat{H}(t)) = & \left[\frac{\partial H(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \right]^2 \cdot \hat{\text{Var}}(\hat{\theta}) \\
& + \left[\frac{\partial H(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \right]^2 \cdot \hat{\text{Var}}(\hat{\beta}) \\
& + 2 \cdot \frac{\partial H(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \cdot \frac{\partial H(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \\
& \cdot \hat{\text{Cov}}(\hat{\theta}, \hat{\beta}), \quad (60)
\end{aligned}$$

where $\hat{\text{Var}}(\hat{\theta})$, $\hat{\text{Var}}(\hat{\beta})$, and $\hat{\text{Cov}}(\hat{\theta}, \hat{\beta})$ are the elements (1,1), (2,2), and (1,2), respectively, of the estimated 2×2 asymptotic variance-covariance matrix $\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta})$, and the partial derivatives of $h(t)$ and $H(t)$ with respect to the model parameters, say

$$\begin{aligned}
\frac{\partial h(t)}{\partial \theta} &= - \left(\frac{\beta}{\theta} \right)^2 \left(\frac{t}{\theta} \right)^{\beta-1} \quad \text{and} \\
\frac{\partial h(t)}{\partial \beta} &= \frac{1}{t} \left(\frac{t}{\theta} \right)^{\beta} \left[1 + \beta \ln \left(\frac{t}{\theta} \right) \right], \quad (61) \\
\frac{\partial H(t)}{\partial \theta} &= - \left(\frac{\beta}{\theta} \right) \left(\frac{t}{\theta} \right)^{\beta} \quad \text{and} \\
\frac{\partial H(t)}{\partial \beta} &= \beta \left(\frac{t}{\theta} \right)^{\beta} \ln \left(\frac{t}{\theta} \right), \quad (62)
\end{aligned}$$

need to be evaluated at the ML estimates $\hat{\theta}$ and $\hat{\beta}$. Note that, for complete samples, the matrix $\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta})$ is approximately [1,20]

$$\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta}) = \begin{bmatrix} \left(\frac{\hat{\theta}}{\hat{\beta}} \right)^2 \frac{1.1087}{n} & \hat{\theta} \cdot \frac{0.2570}{n} \\ \hat{\theta} \cdot \frac{0.2570}{n} & \hat{\beta}^2 \cdot \frac{0.6079}{n} \end{bmatrix}. \quad (63)$$

For small and moderate samples, the approximate $(1 - \alpha)$ confidence intervals (Eqs 31 and 32), based on the lognormal approximation for the distribution of $\hat{h}(t)$ and $\hat{H}(t)$, should work better than the normal approximations, since the lognormal approximation avoids obtaining negative values for the lower confidence limits.

Of course, any other method available for computing confidence limits for $R(t)$ can be

used for deriving confidence limits for $H(t)$. For example, the method suggested by [2] for $R(t)$ gives, as matter of fact, approximate $(1 - \alpha)$ confidence intervals for $U(t) = \ln H(t)$, in the form

$$\begin{aligned}
\hat{U}_L(t) &= \hat{U} + z_{\alpha/2} \\
&\cdot \left[\frac{1.1680 + 1.1000 \hat{U}^2 - 0.1913 \hat{U}}{n} \right]^{1/2}, \quad (64)
\end{aligned}$$

$$\begin{aligned}
\hat{U}_U(t) &= \hat{U} - z_{\alpha/2} \\
&\cdot \left[\frac{1.1680 + 1.1000 \hat{U}^2 - 0.1913 \hat{U}}{n} \right]^{1/2}, \quad (65)
\end{aligned}$$

where $\hat{U} \equiv \ln \hat{H}(t)$. Thus, we simply obtain: $\hat{H}_L(t) = \exp[\hat{U}_L(t)]$ and $\hat{H}_U(t) = \exp[\hat{U}_U(t)]$.

In the case of Type II censored samples, exact $(1 - \alpha)$ upper confidence limits for $H(t)$ can be obtained from the $(1 - \alpha)$ lower confidence limits for $R(t)$ given in Table 7B of Ref. 21, for $n = 40(20)120$, $\hat{R}(t)$ ranging from 0.70 up to 0.999, $\alpha = 0.10, 0.05, 0.02$, and 0.01, and censoring level $r/n = 0.75$ and 0.50. Such limits can be used as approximate limits for Type I censored samples, too. For large samples, approximate confidence intervals for $h(t)$ and $H(t)$ can be obtained from Equations (27) and (28), respectively, whereas for small or moderate samples the approximations (Eqs 31 and 32), based on the lognormal approximation, should work better. The asymptotic variances of $\hat{h}(t)$ and $\hat{H}(t)$ need to be estimated through Equations (29) and (30), respectively, and the asymptotic matrix $\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta})$ is obtained by inverting the estimated information matrix $\hat{\mathbf{J}}(\hat{\theta}, \hat{\beta})$ (Eq 75 in the Appendix). Note that, for singly censored samples, the asymptotic matrix $\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta})$ can be easily read from tables in Ref. 22 as a function of the standardized censoring time $\zeta = [\ln T_C - \ln \hat{\theta}] \hat{\beta}$, where T_C is the censoring time. The matrix is the same for singly censored Type I and II data.

Example 3. Let us consider the Type I censored data referring to $n = 12$ units of

Table 3. Life Test Data of a Certain Type of Electromechanical Device in Example 3

6	3803	1	12	5500	0

an electromechanical device given by Yang [19]. All the tests were stopped at the time $T_C = 5500$ h and $r = 8$ failures were observed at times $t_1, t_2, \dots, t_8$ (Table 3, where $\delta_i = 1$ if the time t_i is an exact failure time, and $\delta_i = 0$ if t_i is a right censored observation). By solving Equation (53), the ML estimate of β is $\hat{\beta} = 2.055$, from which, by using Equation (52) the ML estimate of θ is

$$\hat{\theta} = \left(\frac{\sum_{i=1}^{12} t_i^{2.055}}{8} \right)^{1/2.055} = 5215 \text{ h.} \quad (66)$$

The failure rate and the cumulative failure rate at the time $t = 4000$ h are estimated from Equation (55): $\hat{h}(4000) = 0.000298 \text{ h}^{-1}$ and $\hat{H}(4000) = 0.580$. The approximate 90% confidence intervals for $h(t)$ and $H(t)$ at $t = 4000$ h, based on the lognormal approximations in Equations (31) and (32), result in

$$(\hat{h}_L(4000), \hat{h}_U(4000)) = (0.000153 \text{ h}^{-1}, 0.000580 \text{ h}^{-1}), \quad (67)$$

$$(\hat{H}_L(4000), \hat{H}_U(4000)) = (0.272, 1.235), \quad (68)$$

being

$$\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta}) = \begin{pmatrix} 825042. \text{ h}^2 & -90.815 \text{ h} \\ -90.815 \text{ h} & 0.4117 \end{pmatrix},$$

$$z_{0.050} = -1.645 \quad \hat{\text{Var}}(\hat{h}(4000)) = (0.000121 \text{ h}^{-1})^2, \text{ and}$$

$$\hat{\text{Var}}(\hat{H}(4000)) = (0.2666)^2.$$

GRAPHICAL PROCEDURE: CUMULATIVE HAZARD PLOTS

Estimate of the cumulative failure rate $H(t)$ can be often performed via *cumulative hazard plots* (often simply called *hazard plots* [2]). This procedure can be used in case the random variable T either pertains to the location-scale family or admits a transformation $g(t)$ which leads to a location-scale distribution. More formally, it is required that the cumulative density function $F(t) = 1 - R(t)$ of the random variable T can be expressed as

$$F(t; a, b) = \Phi \left(\frac{g(t) - a}{b} \right), \quad (69)$$

$\Phi(\cdot)$ being a function independent of any unknown parameter, so that, from Equation (3)

$$\begin{aligned} H(t; a, b) &= -\ln \left[1 - \Phi \left(\frac{g(t) - a}{b} \right) \right] \\ &= \Psi \left(\frac{g(t) - a}{b} \right). \end{aligned} \quad (70)$$

The parameters a and b are called *location* and *scale* parameters, respectively.

Then, the hazard plot is obtained by adopting a $g(t)$ scale on the data axis (the x axis) and a $\Psi^{-1}(H)$ scale on the probability axis (the y axis). On this *model-dependent* chart, the plot of $H(t)$ versus t appears as a straight line. For example, in the case of the two-parameter Weibull model, the cumulative failure rate $H(t) = (t/\theta)^\beta$ can be easily linearized as it follows

$$\ln H(t) = \beta \ln t - \beta \ln \theta, \quad (71)$$

so that, for a two-parameter Weibull random variable, $g(T) = \ln T$, $a = \ln \theta$, $b = 1/\beta$, and $\Psi^{-1}(H) = \ln H(t)$.

Commercial hazard plots are generally available (even if sometimes difficult to find) for certain common distributions, such as the standard exponential, the two-parameter Weibull, and the lognormal distributions. From Equation (71), we have that a two-parameter Weibull hazard plot is easy to construct since it has a log scale on both the axes. Even easier is to construct a standard

exponential hazard plot: it has a linear scale on both the axes because for such a model, $H(t) = \lambda t$ so that $g(T) = T, a = 0, b = \lambda$, and $\Psi^{-1}(H) = H(t)$.

In order to use hazard plots, each ordered failure time $t_{(i)}$ ($i = 1, 2, \dots$) against an estimate of $H(t)$ at that time, say H_i , must be plotted on the chart. These estimates of $H(t)$, named *plotting positions*, are obtained via a nonparametric approach. Only failure data are plotted on the hazard plot, and not censoring times. Thus, plotting positions must be evaluated only at failure times.

Once the data are plotted on the chosen hazard plot, it is necessary to fit a straight line through the points $(t_{(i)}, H_i)$, because the use of the plotting positions inevitably produces departure from linearity. Very often the fitting is performed by eyes, but a more accurate fit can be obtained by means of analytical methods, such as the least-squares method [1]. The graphical estimate of $H(x)$ at a given time x of interest is then given by the ordinate (i.e., the value on the cumulative hazard axis) of the point on the straight line having abscissa x .

Plotting Positions

In the case of complete or singly censored samples, the plotting position H_i for the i th ordered failure time $t_{(i)}$ ($i = 1, 2, \dots, r$) can be calculated using Ref. 2 as

$$H_i = \ln \left(\frac{n}{i - 0.5} \right), \quad i = 1, 2, \dots, r, \quad (72)$$

where n is the size of the sample and $r \leq n$ is the number of failure times in the sample. Other plotting positions, such as $H_i = \ln[(n + 1)/i]$, can be used. In the case of multiply censored samples without tied failure times, the plotting position H_i relative to the i th ordered failure time $t_{(i)}$ can be obtained via the following Herd–Johnson-based estimator [2]:

$$H_i = \sum_{j=1}^i \ln \left(\frac{k_j + 1}{k_j} \right), \quad i = 1, 2, \dots, r, \quad (73)$$

where k_i is the number of units at risk immediately before the ordered failure time $t_{(i)}$.

In the case of tied failure times, the plotting position H_i has to be estimated at any distinct (ordered) time $x_{(i)}$ ($i = 1, 2, \dots, s$) at which one or more failures occur, by using the NA estimator [Eq. (16); [1]]:

$$H_i = \sum_{j=1}^i \frac{d_j}{k_j}, \quad i = 1, 2, \dots, s, \quad (74)$$

where d_j denotes the number of failures that occurred at $x_{(j)}$.

Example 1 (continued). By using the winding data of Table 1, we can estimate via a graphical procedure, the cumulative failure rate of the electromechanical devices at the times $t = 50$ months and $t = 200$ months, under the assumption that failure times follow a two-parameter Weibull distribution. The plotting positions H_i are estimated via the NA estimator (Eq. 74) for each ordered failure time $t_{(i)}$ ($i = 1, 2, \dots, 8$), as given in the fifth column of Table 2 [note that, because there are no tied failure times, the Herd–Johnson-based estimator (Eq. 73) could also be used]. Once points $(t_{(i)}, H_i)$ are plotted on a Weibull hazard plot (i.e., a plot with both log scales) and the straight line is fitted by eye, the graphical estimates of the cumulative failure rate are $\hat{H}(50) = 0.19$ and $\hat{H}(200) = 2.5$, as depicted in Fig. 2. Using the least-squares method, we have $\hat{H}(50) = 0.173$ and $\hat{H}(200) = 2.941$, respectively. Note that, unlike the nonparametric procedure, the use of hazard plots allows $H(t)$ to be estimated also for t values greater than the largest failure or censoring time.

APPENDIX

The estimated $l \times l$ asymptotic variance–covariance matrix $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ of the parameter vector $\boldsymbol{\theta} = (\theta_1, \theta_2, \dots, \theta_l)$ is the inverse of the estimated information matrix $\hat{\mathbf{J}}(\hat{\boldsymbol{\theta}})$, whose entries are the negative second derivatives of the log-likelihood function $\ell(\boldsymbol{\theta}; t)$ with respect to the model parameters $\boldsymbol{\theta}$ evaluated at the ML estimates $\hat{\boldsymbol{\theta}} : \hat{\mathbf{V}}(\hat{\boldsymbol{\theta}}) = [\hat{\mathbf{J}}(\hat{\boldsymbol{\theta}})]^{-1}$.

For a right censored sample $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ from a two-parameter Weibull

Figure 2. Graphical estimate of $H(50)$ and $H(200)$ in Example 1.

distribution with scale parameter θ and shape parameter β (refer section titled “Data from the Two-Parameter Weibull

Distribution”), the estimated 2×2 information matrix results in

$$\hat{\mathbf{J}}(\hat{\theta}, \hat{\beta}) = \begin{pmatrix} r \left(\frac{\hat{\beta}}{\hat{\theta}} \right)^2 & -\frac{\hat{\beta}}{\hat{\theta}} \sum_{i=1}^n \left(\frac{t_i}{\hat{\theta}} \right)^{\hat{\beta}} \ln \left(\frac{t_i}{\hat{\theta}} \right) \\ -\frac{\hat{\beta}}{\hat{\theta}} \sum_{i=1}^n \left(\frac{t_i}{\hat{\theta}} \right)^{\hat{\beta}} \ln \left(\frac{t_i}{\hat{\theta}} \right) & \frac{r}{\hat{\beta}^2} + \sum_{i=1}^n \left(\frac{t_i}{\hat{\theta}} \right)^{\hat{\beta}} \left[\ln \left(\frac{t_i}{\hat{\theta}} \right) \right]^2 \end{pmatrix}, \quad (75)$$

where r ($r \leq n$) is the number of exact failure times.

The *complete* (or conditional) *intensity function* (CIF) of the stochastic point process $\{N(t) : t \geq 0\}$ is defined as

$$\lambda(t; H_t) = \lim_{\Delta t \rightarrow 0} \frac{\Pr\{N(t, t + \Delta t) \geq 1 | H_t\}}{\Delta t}, \quad (1)$$

where $N(t, t + \Delta t)$ denotes the (integer-valued) random variable counting the number of failures that occur in the time interval $(t, t + \Delta t]$, and $H_t = \{N(0, s) : 0 \leq s \leq t\}$ represents the entire *history* of the process up to time t [1]. The way in which the history affects the CIF depends mainly on the kind of repair actions performed on the system. For example, if the system is renewed at each failure, then the history affects the CIF only through the occurrence time of the most recent failure prior to t , say $t_{N(t)}$, and the CIF at time t is a function of the time elapsed from $t_{N(t)}$ until t , say $\lambda(t; H_t) = \lambda(t - t_{N(t)})$. If the system is minimally repaired at failure, then the CIF does not depend on the history of the process but only, at the most, on time t . More complex forms for the CIF arise when the system is subject to imperfect repairs or to a maintenance policy consisting of a sequence of corrective repairs interspersed with major overhauls [2,3].

For small Δt values, the product $\lambda(t; H_t) \cdot \Delta t$ is approximately equal to the conditional probability that at least one failure (not necessarily the first) occurs in the time interval $(t, t + \Delta t]$, given the history up to t [4].

The expectation of the number $N(t) = N(0, t)$ of failures up to t , known as the *mean value function* $M(t) = E\{N(t)\}$, is a nondecreasing right continuous function. Its first derivative $v(t) = dM(t)/dt$, if it exists, is called the *rate of occurrence of failures* (ROCOF) and represents the time rate of change of $M(t)$ [5].

If simultaneous failures cannot occur, so that the arrival times of failures are distinct, then $M(t)$ is continuous everywhere and the point process is said to be *orderly* or *regular* [5,6]. Under orderliness conditions, the ROCOF function $v(t)$, if it exists, numerically equals the (*unconditional*) intensity function $\lambda(t)$ which is defined as

$$\lambda(t) = \lim_{\Delta t \rightarrow 0} \frac{\Pr\{N(t, t + \Delta t) \geq 1\}}{\Delta t}, \quad (2)$$

and can be viewed as the expectation of the CIF (Eq. 1) over the entire space of possible histories. Of course, under orderliness conditions, the cumulative intensity function $\Lambda(t) = \int_0^t \lambda(z) dz$ numerically equals the mean value function $M(t)$.

If the CIF does not depend on H_t but only, at the most, on the operating time (i.e., the failure probability is unchanged by failure and successive repair), then the two intensity functions (Eqs 1 and 2) coincide. Also, for small Δt , the product $\lambda(t) \cdot \Delta t$ is approximately equal to the (unconditional) probability that at least one failure occurs in the time interval $(t, t + \Delta t]$ [6]. If the point process $\{N(t)\}$ is not orderly, then the ROCOF is greater than the intensity function $\lambda(t)$ [1] and does not specify the process uniquely [4].

The behavior of the intensity function $\lambda(t)$ and of the mean value function $M(t)$ is very representative of the failure/repair process. For example, a decreasing intensity function [or, equivalently, a downward concave $M(t)$] shows that failures become less and less frequent with the operating time t , whereas an increasing intensity function [or, equivalently, an upward concave $M(t)$] gives evidence of more and more frequent failures

with t . These situations are commonly known as *reliability growth* or *improvement* and *reliability decay* or *deterioration*.

Nonparametric and parametric estimation procedures of the intensity function and of the mean value function are available for data arising from both, a single repairable system and a multiple repairable system.

DATA FROM A SINGLE REPAIRABLE SYSTEM

Let $t_1 < t_2 < \dots < t_n \leq T$ denote the n failure times of a repairable system operating up to time T . Suppose that repair times are negligible, or are measured on a different timescale, so that the interarrival times $x_i = t_i - t_{i-1}$ (where $t_0 = 0$ and $i = 1, 2, \dots, n$) represent the operating times between the $(i-1)$ th and i th failures. A number of nonparametric and parametric estimation procedures for $\lambda(t)$ and $M(t)$ are illustrated. The main difference between the two procedures consists of the fact that, unlike the parametric one, the nonparametric procedure does not allow $\lambda(t)$ and $M(t)$ to be estimated for t values outside the observation interval $[0, T]$. In addition, nonparametric estimation generally provides only point estimates of $\lambda(t)$ and $M(t)$, and not interval estimation.

Nonparametric Estimators

A natural nonparametric estimate of $M(t)$ at the time t is given by the observed number of failures that occurred until t , say

$$\tilde{M}(t) = N(t), t \leq T. \quad (3)$$

It is a staircase function, that is, the function $\tilde{M}(t)$ is flat between successive failure times, equal to i ($i = 1, 2, \dots, n$) at $t = t_i$, but in a graphical representation of $\tilde{M}(t)$ only the points (t_i, i) need to be plotted and not the flat portions [7]. Of course, the true mean value function of a large population of identical systems operating under identical working conditions should be regarded as a smooth curve, so that it is useful to imagine a smooth curve which passes through the plotted points (t_i, i) .

From Equation (3), an estimate of the mean ROCOF function over each interval

$(t_{i-1}, t_i]$ ($i = 1, 2, \dots, n$) easily follows:

$$\tilde{v}(t) = \frac{1}{t_i - t_{i-1}}, \quad t_{i-1} < t \leq t_i, \quad i = 1, 2, \dots, n. \quad (4)$$

It is worth noting that, under orderliness conditions, any estimate of the ROCOF provides an estimate of $\lambda(t)$, too; similarly, any estimate of $M(t)$ provides an estimate of the cumulative intensity function $\Lambda(t)$. The graph of the estimator (Eq. 4) generally appears jagged, moving up when two successive failures are close each other, and down when the failures are sparse. A smoother estimator of $v(t)$ can be obtained by partitioning the observation interval $[0, T]$ into k subintervals: $[0, \tau_1], [\tau_1, \tau_2], \dots, [\tau_{k-1}, \tau_k]$, where $0 < \tau_1 < \dots < \tau_{k-1} < \tau_k = T$. These subintervals may be of equal length, but this is not necessary. If $N(\tau_{l-1}, \tau_l) = N(\tau_l) - N(\tau_{l-1})$ denotes the number of failures that occurred in the l th subinterval ($l = 1, 2, \dots, k$), then the estimate of the ROCOF function $v(t)$ is

$$\bar{v}(t) = \frac{N(\tau_{l-1}, \tau_l)}{\tau_l - \tau_{l-1}}, \quad \tau_{l-1} < t \leq \tau_l, l = 1, \dots, k, \quad (5)$$

where $\tau_0 = 0$ and $N(\tau_0) = 0$ [8]. The estimator (Eq. 5) is particularly suitable when the available data are aggregated, that is, they consist of the number of failures occurring in given nonoverlapping intervals, and not in the individual failure times. From Equation (5), an estimator of $M(t)$ suitable for aggregate data follows:

$$\bar{M}(t) = N(\tau_{l-1}) + \frac{t - \tau_{l-1}}{\tau_l - \tau_{l-1}} N(\tau_{l-1}, \tau_l), \quad \tau_{l-1} < t \leq \tau_l, l = 1, \dots, k; \quad (6)$$

this is a piecewise-linear function equal to $N(\tau_l)$ at $t = \tau_l$.

Another nonparametric estimate of $v(t)$, called a *natural estimate* in Ref. 5, is the following:

$$\bar{v}_{\text{nat}}(t) = \frac{N(t, t + \Delta t)}{\Delta t}, \quad (7)$$

which looks at the number $N(t, t + \Delta t)$ of failures that occurred in a moving window of

Figure 1. Nonparametric estimate of the mean value function $M(t)$ for the data in Example 1.

prefixed length Δt . When Δt is small, the plot of $\bar{v}_{\text{nat}}(t)$ will appear jagged, moving down when the failures are sparse, and up when the failures are frequent. Of course, the estimator in Equation (7) is seriously biased when t is in the interval $[T - \Delta t, T]$ because, when $t > T - \Delta t$, the interval $[t, t + \Delta t]$ will include times beyond the observation period. Thus, $\bar{v}_{\text{nat}}(t)$ should be calculated only for $0 \leq t \leq T - \Delta t$ [8].

Under orderliness conditions, a kernel smoothing of the estimated increments of $M(t)$ from time t_{i-1} up to t_i ($i = 1, 2, \dots, n$), say $\Delta \tilde{M}_i = \tilde{M}(t_i) - \tilde{M}(t_{i-1}) = 1$, provides a smooth estimate of $v(t)$ and $\lambda(t)$ as given by Lewis and Shedler [9]:

$$\tilde{v}_k(t) = \frac{1}{b_n} \sum_{i=1}^n W\left(\frac{t - t_i}{b_n}\right), \quad (8)$$

where b_n is a sequence of smoothing parameters, known as the *bandwidth*, satisfying $b_n \rightarrow 0$ but $nb_n \rightarrow \infty$ as the sample size $n \rightarrow \infty$, and the *kernel function* $W(z)$ is a bounded nonnegative weight function which satisfies $\int_{-\infty}^{\infty} W(z) dz = 1$. $W(z)$ is typically assumed to be a symmetric probability density function with zero mean and unit variance. For example, $W(z)$ can be the normal density function. The level of smoothness is set by the bandwidth b_n : the larger b_n , the smoother $\tilde{v}_k(t)$ is.

Example 1. Let us consider the failure data of the power-train system of a bus #524 built by Breda Menarinibus which consists of 47 failure times (in km) observed until $T = 373,716$ km [10]. Figure 1 depicts the nonparametric estimate $\tilde{M}(t)$ for such data. The imaginary smooth curve which passes through the plotted points (t_i, i) ($i = 1, 2, \dots, 47$) is upward concave, thus giving graphical evidence of reliability deterioration with t . Note that this analysis (as well as the following one) is for illustration purposes only. Figure 2 gives the plots of nonparametric estimates (Eqs 5 and 7) and of the kernel estimate, Equation (8), of the ROCOF $v(t)$: the plot of estimate 5, obtained by partitioning the interval $[0, T]$ into 8 subintervals of equal length of 46,714.5 km, is much less jagged than the plot of the natural estimate (7), obtained by setting $\Delta t = 20,000$ km. The kernel estimate $\tilde{v}_k(t)$ is obtained by setting $b_n = 20,000$ km, and using a normal density function as the kernel function. Accordingly, with the plot of $\tilde{M}(t)$ in Fig. 1, all the plots of Fig. 2 give evidence of increasing ROCOF (and intensity function) with operating time at least until $t = 200,000$ km, then becoming almost constant.

Parametric Estimators

Parametric estimation procedures imply the choice of a stochastic model able

Figure 2. (a) Nonparametric, (b) natural, and (c) kernel estimates of $v(t)$ for the data in Example 1.

to adequately describe the observed failure/repair process. Such a choice should be based on technical information about the type of maintenance policy being employed and its effect on the operating conditions of the system. Of course, the

effect of maintenance actions depends not only on the action that is performed (repair or substitution of the failed part, major overhaul of the system, and so on) but also on the physical structure and complexity of the system.

Parametric estimation, based on the maximum likelihood method, is provided here for two special cases: (i) the system is subject to minimal repair (after repair, the system is in exactly the same condition it was in just before the failure) and its failure pattern does not show any trend with operating time t ; and (ii) the system is minimally repaired but can experience reliability improvement or deterioration with t . In the first case, the failure process is described through a homogeneous Poisson process (HPP) and in the second case a non-homogeneous Poisson process (NHPP) with power-law intensity (called the *Power-Law process*, PLP) is adopted here. Note that there are many choices for the intensity and the PLP is the simplest one for analytical procedures.

Homogeneous Poisson Process. The HPP is a Poisson process with constant intensity function $\lambda(t; H_t) = \lambda(t) = \lambda$, and times between successive failures, say $x_i = t_i - t_{i-1}$ ($i = 1, 2, \dots$), are independent and identically exponentially distributed random variables with mean $1/\lambda$. Since times between failures are independent and identically distributed random variables, then the HPP is also a renewal process. Due to the orderliness property of the Poisson processes, the ROCOF is equal to λ , too, and the mean value function is $M(t) = \lambda t$.

If the data arise from failure-truncated testing, that is, the process is observed up to the occurrence of a prefixed n th failure, the maximum likelihood estimate (MLE) of the intensity function is

$$\hat{\lambda} = n/t_n, \quad (9)$$

where t_n is the last failure time [8]. Since the quantity $2\lambda t_n$ is distributed as a chi-square random variable with $2n$ degrees of freedom, the equal-tail $(1 - \alpha)$ confidence interval for λ is

$$\left(\frac{\chi_{1-\alpha/2}^2(2n)}{2t_n}, \frac{\chi_{\alpha/2}^2(2n)}{2t_n} \right), \quad (10)$$

where $\chi^2(2n)$ denotes the critical value of the chi-square distribution with $2n$ degrees

of freedom. Due to the invariance property of the maximum likelihood estimators, the MLE of the mean value function is

$$\hat{M}(t) = t\hat{\lambda} = nt/t_n, \quad (11)$$

and the equal-tail $(1 - \alpha)$ confidence interval for $M(t)$ is

$$\left(\frac{t\chi_{1-\alpha/2}^2(2n)}{2t_n}, \frac{t\chi_{\alpha/2}^2(2n)}{2t_n} \right). \quad (12)$$

If the process is time truncated, that is, the testing is stopped at a prefixed time T , so that the number n of observed failures is random, the MLE of the intensity function is

$$\hat{\lambda} = n/T, \quad (13)$$

and the approximate equal-tail $(1 - \alpha)$ confidence interval for λ is [11]

$$\left(\frac{\chi_{1-\alpha/2}^2(2n)}{2T}, \frac{\chi_{\alpha/2}^2(2n+2)}{2T} \right). \quad (14)$$

The confidence interval in Equation (14) is conservative in the sense that the probability that it covers the true λ value in repeated sampling is equal to $(1 - \alpha)$ or greater. The MLE of the mean value function is

$$\hat{M}(t) = t\hat{\lambda} = nt/T, \quad (15)$$

and the conservative equal-tail $(1 - \alpha)$ confidence interval for $M(t)$ is

$$\left(\frac{t\chi_{1-\alpha/2}^2(2n)}{2T}, \frac{t\chi_{\alpha/2}^2(2n+2)}{2T} \right). \quad (16)$$

From Equations (11) and (15), we find that the MLE of the mean value function at the testing stopping time, say $\hat{M}(t_n)$ or $\hat{M}(T)$ for failure or time-truncated process, is equal to the observed number n of failures.

Power-Law Process. The Power-Law process is the best known and most frequently used NHPP. Its intensity function is given by Ref. 12 as

$$\lambda(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1}. \quad (17)$$

The intensity function (Eq. 17) can increase or decrease with t depending on whether the power-law parameter β is greater or smaller than 1. Thus, the PLP can describe both, reliability deterioration and improvement. If $\beta = 1$, the PLP reduces to the HPP. The expected number of failures $M(t) = (t/\theta)^\beta$ is linear with t on a log-log scale: $\ln[M(t)] = \beta \ln t - \beta \ln \theta$. Hence, if a failure data set follows the PLP, the plot of the cumulative number of failures $N(t_i) = i$ ($i = 1, 2, \dots$) versus the observed failure times t_i should be reasonably close to a straight line with slope β on log-log paper.

If the process is observed up to the occurrence of a prefixed n th failure (failure-truncated testing), the MLE of the PLP parameters is

$$\hat{\beta} = \frac{n}{\sum_{i=1}^n \ln(t_n/t_i)} \text{ and } \hat{\theta} = \frac{t_n}{n^{1/\hat{\beta}}}, \quad (18)$$

[12] and the MLE of the intensity function and of the mean value function, at a given time t , result in

$$\hat{\lambda}(t) = \frac{n\hat{\beta}}{t} \left(\frac{t}{t_n} \right)^{\hat{\beta}} \text{ and } \hat{M}(t) = n \left(\frac{t}{t_n} \right)^{\hat{\beta}}. \quad (19)$$

Simulation bounds on the cumulative number of events can be plotted [13] or approximate confidence intervals for $\lambda(t)$ and $M(t)$ can be obtained by applying the Delta method. The latter method allows approximated standard deviation of $\hat{\lambda}(t)$ and $\hat{M}(t)$ to be estimated once the first derivatives of $\lambda(t)$ and $M(t)$, with respect to the PLP parameters, have been evaluated at the MLE

$\hat{\theta}$ and $\hat{\beta}$:

$$\hat{\sigma}(\hat{\lambda}(t)) = \left[\hat{C}_{1,1} \left(\frac{\partial \lambda(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \right)^2 + 2\hat{C}_{1,2} \times \frac{\partial \lambda(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \frac{\partial \lambda(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} + \hat{C}_{2,2} \left(\frac{\partial \lambda(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \right)^2 \right]^{1/2}, \quad (20)$$

$$\hat{\sigma}(\hat{M}(t)) = \left[\hat{C}_{1,1} \left(\frac{\partial M(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \right)^2 + 2\hat{C}_{1,2} \times \frac{\partial M(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \frac{\partial M(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} + \hat{C}_{2,2} \left(\frac{\partial M(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \right)^2 \right]^{1/2}, \quad (21)$$

where $\hat{C}_{l,k}$ ($l, k = 1, 2$) denotes the (l, k) entry in the estimated covariance matrix $\mathbf{C}(\hat{\theta}, \hat{\beta})$ and

$$\begin{aligned} \frac{\partial \lambda(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} &= - \left(\frac{\hat{\beta}}{\hat{\theta}} \right)^2 \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}-1}, \\ \frac{\partial \lambda(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} &= \frac{1}{t} \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}} \left[1 + \hat{\beta} \ln \left(\frac{t}{\hat{\theta}} \right) \right], \\ \frac{\partial M(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} &= - \left(\frac{\hat{\beta}}{\hat{\theta}} \right) \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}}, \\ \frac{\partial M(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} &= \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}} \hat{\beta} \ln \left(\frac{t}{\hat{\theta}} \right). \end{aligned} \quad (23)$$

Hence, according to the approximation chosen for the asymptotic distribution of $\hat{\lambda}(t)$ and $\hat{M}(t)$, namely, the normal or the log-normal approximation, the approximate equal-tail $(1 - \alpha)$ confidence intervals for $\lambda(t)$ and $M(t)$ result in either

$$\hat{\lambda}(t) \pm z_{\alpha/2} \hat{\sigma}(\hat{\lambda}(t)) \text{ and } \hat{M}(t) \pm z_{\alpha/2} \hat{\sigma}(\hat{M}(t)) \quad (24)$$

or

$$\begin{aligned} \hat{\lambda}(t) \cdot \exp\{\pm z_{\alpha/2} \hat{\sigma}(\hat{\lambda}(t))/\hat{\lambda}(t)\} \text{ and} \\ \hat{M}(t) \cdot \exp\{\pm z_{\alpha/2} \hat{\sigma}(\hat{M}(t))/\hat{M}(t)\}, \end{aligned} \quad (25)$$

where $z_{\alpha/2}$ is the $\alpha/2$ critical value of the standard normal distribution. Since both $\lambda(t)$ and $M(t)$ are constrained to be nonnegative, the log-normal approximation should work better when the sample size is not large because it avoids negative lower confidence limits to be obtained, as often occurs under the normal approximation for small or moderate sample sizes.

For $t = t_n$, the MLE of the mean number of failures is $\hat{M}(t_n) = n$, that is, it equals the observed number of failures, and the MLE of $\lambda(t_n)$ is

$$\hat{\lambda}(t_n) = \frac{n\hat{\beta}}{t_n}. \quad (26)$$

The estimator in Equation (26) is highly biased for small n [14], since

$$E\{\hat{\lambda}(t_n)\} = \frac{n^2}{(n-1)(n-2)} \hat{\lambda}(t_n), \quad (27)$$

so that an unbiased estimators of $\lambda(t_n)$ results in the following equation [14]:

$$\hat{\lambda}_U(t_n) = \frac{(n-1)(n-2)\hat{\beta}}{nt_n}. \quad (28)$$

Note that the value of the intensity function when testing stops is a very important quantity for a system undergoing a reliability growth program. Indeed, this quantity represents the intensity for the system if it were put into service with no further improvements, and its estimate is generally used to decide when the reliability growth program can be stopped. On the other hand, for a system experiencing reliability deterioration, the estimate of that value of the intensity function can be used to decide when to remove the system from use or when to overhaul it.

By using the result that the quantity $\Omega = 4n^2\lambda(t_n)/\hat{\lambda}(t_n)$ is distributed as the product of two independent chi-square random variables with $2(n-1)$ and $2n$ degrees of freedom [15], respectively, $(1-\alpha)$ confidence intervals for $\lambda(t_n)$ are

$$(\omega_1 \hat{\lambda}(t_n), \omega_2 \hat{\lambda}(t_n)), \quad (29)$$

where ω_1 and ω_2 are, respectively, the $\alpha/2$ and $(1-\alpha/2)$ quantiles of the distribution of $\Omega/(4n^2)$, and can be read from Ref. 8 (Table A.4) for selected values of α and $n = 2(1)100$ (values of $1/\omega_1$ and $1/\omega_2$ can be found in Table 1 of Ref. 16. For large n values, say $n \geq 100$, approximate $(1-\alpha)$ confidence intervals for $\lambda(t_n)$ are given by Crow [16]:

$$\left([1 + z_{\alpha/2}\sqrt{2/n}] \hat{\lambda}(t_n), [1 - z_{\alpha/2}\sqrt{2/n}] \hat{\lambda}(t_n) \right). \quad (30)$$

If testing is stopped at a prefixed time T the MLE of the PLP parameters [12] is

$$\hat{\beta} = \frac{n}{\sum_{i=1}^n \ln(T/t_i)} \quad \text{and} \quad \hat{\theta} = \frac{T}{n^{1/\hat{\beta}}}, \quad (31)$$

and the MLE of the intensity function and the mean value function, at a given time t , result in

$$\hat{\lambda}(t) = \frac{n\hat{\beta}}{t} \left(\frac{t}{T} \right)^{\hat{\beta}} \quad \text{and} \quad \hat{M}(t) = n \left(\frac{t}{T} \right)^{\hat{\beta}}. \quad (32)$$

As in the case of failure-truncated testing, approximate confidence intervals for $\lambda(t)$ and $M(t)$ can be obtained by applying the Delta method and using the estimated covariance matrix $\mathbf{C}(\hat{\theta}, \hat{\beta})$.

For $t = T$, the MLE of the mean number of failures is $\hat{M}(T) = n$, that is, it equals the observed number of failures, and the MLE of the intensity function is

$$\hat{\lambda}(T) = \frac{n\hat{\beta}}{T}. \quad (33)$$

Approximate equal-tail $(1-\alpha)$ confidence intervals for $\lambda(T)$ can be obtained from

$$(\rho_1 \hat{\lambda}(T), \rho_2 \hat{\lambda}(T)), \quad (34)$$

where ρ_1 and ρ_2 are listed in Ref. 8 (Table A.5) for selected values of α and $n = 2(1)100$ (values of $1/\rho_1$ and $1/\rho_2$ can be found in Table 2 of Ref. 16. For large n values, say $n \geq 100$, approximate $(1-\alpha)$ confidence

Table 1. Failure Times (in km) of the Power-Train System of Bus #524^a

19,635	53,464	54,125	70,207	71,161	71,687	131,964	132,123	137,412	137,988

^aFrom Ref. 10, and to be read across the row).

intervals for $\lambda(T)$ are given by either of these equations [16]:

$$\left(\left[\frac{n + z_{\alpha/2}^2/4 - \sqrt{n z_{\alpha/2}^2/2 + z_{\alpha/2}^4/16}}{n} \right]^2 \hat{\lambda}(T), \left[\frac{n + z_{\alpha/2}^2/4 + \sqrt{n z_{\alpha/2}^2/2 + z_{\alpha/2}^4/16}}{n} \right]^2 \hat{\lambda}(T) \right) \quad (35)$$

or

$$\left((1 + z_{\alpha/2}/\sqrt{2n})^2 \hat{\lambda}(T), (1 - z_{\alpha/2}/\sqrt{2n})^2 \hat{\lambda}(T) \right). \quad (36)$$

Approximation from Equation (35) provides more accurate upper confidence limits, whereas lower limits are better approximated by Equation (36). A slightly different approximation can be found in Ref. 17.

Example 1 (continued). Let us continue considering the power-train data of Table 1. By assuming that the power-train system was very likely subject to deterioration phenomena with operating time and has undergone minimal repair at failure, the PLP is chosen to analyze the failure data. From Equation (31), the MLE of parameters are $\hat{\beta} = 1.555$ and $\hat{\theta} = 31422$ km. Figure 3 depicts the MLE of $M(t)$ together with the approximate 95% confidence interval, obtained by applying the Delta methods

and using the log-normal approximation for the distribution of $\hat{M}(t)$. The nonparametric estimate (Eq. 3), that is the points (t_i, i) ($i = 1, 2, \dots, 47$), is also depicted. Figure 3 shows a good fit of the PLP model to the observed failures. The approximate 95% confidence interval for $\lambda(T)$, based on the Delta method and the log-normal approximation for the distribution of $\hat{\lambda}(T)$, is compared in Table 2 to the confidence interval provided by Equation (34) and to the asymptotic approximations of Equations (35) and (36).

DATA FROM MULTIPLE REPAIRABLE SYSTEMS

A number of nonparametric and parametric estimation procedures for $\lambda(t)$ and $M(t)$ are available when failure data t_{ij} arise from m identical repairable systems, where t_{ij} denotes the i th failure time ($i = 1, 2, \dots, n_j$) from the j th system ($j = 1, 2, \dots, m$) observed over the interval $[0, T_j]$. Both common and uncommon observation periods for each system are considered.

Nonparametric Estimators

Let z_l ($l = 1, 2, \dots, N'$) denote the ordered *distinct* times at which failures of the observed systems occur, where N' is less than or equal to the total number of failures,

Table 2. Approximate 95% Confidence Intervals on $\lambda(T)$ (1/km) for the Data in Example 1

	Delta Method	Equation (34)	Equation (35)	Equation (36)
Lower limit	0.0001305	0.0001248	0.0001306	0.0001245
Upper limit	0.0002930	0.0002927	0.0002926	0.0002826

Figure 3. Nonparametric and MLE estimates of the mean value function $M(t)$ for the data in Example 1.

say $N = \sum_{j=1}^m n_j$, since data arise from multiple systems and some failure times can be tied. In addition, let δ_l ($l = 1, 2, \dots, N'$) denote the number of failures having occurred at z_l , so that $\sum_{l=1}^{N'} \delta_l = N$.

If censoring times T_j 's are common over all the systems, say $T_1 = T_2 = \dots = T_m = T$, then a nonparametric estimate of $M(t)$ at the time $t \leq T$ is given by the equation from Crowder *et al.* [18]:

$$\tilde{M}_C(t) = \frac{\sum_{j=1}^m N_j(t)}{m} = \frac{\sum_{l: z_l \leq t} \delta_l}{m}, \quad (37)$$

where $N_j(t)$ is the number of failures experienced by the j th system up to t .

If times T_j s are uncommon, than a nonparametric estimate of $M(t)$ is given by the recursive formula from Ref. 7:

$$\tilde{M}_U(t) = \tilde{M}_U(z_{l-1}) + \frac{\delta_l}{r(z_l)}, \quad z_{l-1} < t \leq z_l, l = 1, 2, \dots, \quad (38)$$

where $z_0 = 0$, $\tilde{M}_U(z_0) = 0$, and $r(z_l) \leq m$ is the number of systems at risk at time z_l which equals the total number of systems minus the number of systems censored before z_l . However, if the censoring time T_j of the j th system does not coincide with a failure time of that or another system, say $z_{l-1} < T_j < z_l$, the survival time interval (z_{l-1}, T_j) of the j th system is neglected by estimator (38),

and then it can overestimate $M(t)$. To take into account such possible survival times, the estimator from Ref. 10

$$\tilde{M}_T(t) = \tilde{M}_T(z_{l-1}) + \frac{\delta_l}{\text{TOT}(z_{l-1}, z_l)/(z_l - z_{l-1})}, \quad z_{l-1} < t \leq z_l, l = 1, 2, \dots, \quad (39)$$

can be used, where $\tilde{M}_T(z_0) = 0$ and $\text{TOT}(z_{l-1}, z_l)$ is the total operating time of all the observed systems during the time interval (z_{l-1}, z_l) . Each ratio $\text{TOT}(z_{l-1}, z_l)/(z_l - z_{l-1})$ represents an equivalent number of systems operating during the interval (z_{l-1}, z_l) ; it equals $r(z_l)$ if no system has been censored in that interval, and is included between $r(z_l)$ and $r(z_{l-1})$ if one or more systems have been censored in (z_{l-1}, z_l) . Then $\tilde{M}_T(t) \leq \tilde{M}_U(t)$, the equality holding when all censoring time prior to t coincide with a failure time.

Estimators (37), (38), and (39) are staircase functions which are flat between successive failure times z_l , but in a graphical representation of $\tilde{M}(t)$ only the points $(z_l, \tilde{M}_\bullet(z_l))$ ($l = 1, 2, \dots, N'$) need to be plotted, and not the flat portions. The true mean value function of a large population of identical systems operating under identical working conditions should be regarded as a smooth curve, so that it is useful to imagine a smooth curve which passes through the plotted points $(z_l, \tilde{M}_\bullet(z_l))$.

From Equations (37), (38), and (39), nonparametric estimates of the mean ROCOF

function over the interval $(z_{l-1}, z_l]$ easily follow, for common and uncommon times T_j s

$$\begin{aligned}\tilde{v}_C(t) &= \frac{\delta_l}{m \cdot (z_l - z_{l-1})}, \\ \tilde{v}_U(t) &= \frac{\delta_l}{r(z_l) \cdot (z_l - z_{l-1})}, \\ \tilde{v}_T(t) &= \frac{\delta_l}{\text{TOT}(z_{l-1}, z_l)}, z_{l-1} < t \leq z_l. \quad (40)\end{aligned}$$

Under orderliness conditions, any estimate of the ROCOF function provides an estimate of $\lambda(t)$ too. The graphs of the estimators (Eq. 40) generally appear jagged, especially when the number of observed systems is not large.

A kernel smoothing of the estimators $\tilde{M}_\bullet(z_l)$ ($l = 1, 2, \dots, N'$) provides smooth estimates of the ROCOF function

$$\begin{aligned}\tilde{v}_{\bullet,k}(t) &= \frac{1}{b_{N'}} \sum_{l=1}^{N'} W\left(\frac{t - z_l}{b_{N'}}\right) \\ &\quad \cdot [\tilde{M}_\bullet(z_l) - \tilde{M}_\bullet(z_{l-1})], \quad (41)\end{aligned}$$

where the *bandwidth* $b_{N'}$ satisfies $b_{N'} \rightarrow 0$ and $N'b_{N'} \rightarrow \infty$ as $N' \rightarrow \infty$, and the *kernel function* $W(z)$ is a bounded nonnegative weight function satisfying $\int_{-\infty}^{\infty} W(z)dz = 1$.

In case of common censoring times T_j 's, the observation interval $[0, T]$ can be partitioned into k subintervals: $[0, \tau_1]$, $(\tau_1, \tau_2]$, $\dots$, $(\tau_{k-1}, \tau_k]$, with $0 < \tau_1 < \dots < \tau_{k-1} < \tau_k = T$, which may be of equal or unequal length. If $N_j(\tau_l)$ denotes the number of failures experienced by the j th system until τ_l ($l = 1, 2, \dots, k$) and $N_j(\tau_{l-1}, \tau_l) = N_j(\tau_l) - N_j(\tau_{l-1})$, then the estimate of $M(t)$ is as follows [19]:

$$\begin{aligned}\bar{M}(t) &= \frac{1}{m} \sum_{j=1}^m N_j(\tau_{l-1}) + \frac{t - \tau_{l-1}}{\tau_l - \tau_{l-1}} \cdot \frac{1}{m} \\ &\quad \times \sum_{j=1}^m N_j(\tau_{l-1}, \tau_l), \tau_{l-1} < t \leq \tau_l, \\ &\quad l = 1, \dots, k. \quad (42)\end{aligned}$$

The estimator (42) is a piecewise-linear function and is particularly suitable when the available data are aggregated; that

is, they consist of the number of failures occurring in given nonoverlapping intervals, common over all the systems, and not in the individual failure times. From Equation (42), a smoother estimator of the mean ROCOF over the subinterval $(\tau_{l-1}, \tau_l]$ easily follows:

$$\begin{aligned}\bar{\mu}(t) &= \frac{1}{\tau_l - \tau_{l-1}} \cdot \frac{1}{m} \sum_{j=1}^m N_j(\tau_{l-1}, \tau_l), \\ \tau_{l-1} < t \leq \tau_l, l &= 1, \dots, k. \quad (43)\end{aligned}$$

Another nonparametric estimate of $\nu(t)$, called a *natural estimate* in Ref. 5, is

$$\bar{\nu}_{\text{nat}}(t) = \frac{1}{r(t)} \cdot \frac{\sum_{j=1}^m N_j(t, t + \Delta t)}{\Delta t}, \quad (44)$$

where $r(t) \leq m$ is the number of systems at risk at the operating time t , and $N_j(t, t + \Delta t)$ is the number of failures experienced by the j th system in a moving window of prefixed length Δt . Of course, $N_j(t, t + \Delta t) = 0$ for $t \geq T_j$. When Δt is small, the plot of $\bar{\nu}_{\text{nat}}(t)$ will appear jagged, moving down when the failures are sparse, and up when the failures are frequent. The estimator (44) is biased when one or more systems are censored in the interval $(t, t + \Delta t]$.

Example 2. Let us consider the failure data (in h) of 4 air-conditioning systems equipping Boeing 720 aircrafts, namely Plane #1, #2, #3, and #4, as given in Table 3 and copied out from a larger data set in Ref. 10. Suppose that the failure processes of Planes #1 and #2 were truncated at the occurrence of the sixth and ninth failure respectively, so that $T_1 \equiv t_{6,1} = 493$ h and $T_2 \equiv t_{9,2} = 1800$ h, whereas Planes #3 and #4 were observed up to time $T_3 = 800$ h and $T_4 = 648$ h respectively; they had experienced 6 and 2 failures, respectively. Then, a total of $N = 23$ no tied-failures were observed over a total operating time of 3741 h, so that $\delta_l = 1$ for $l = 1, 2, \dots, 23$ and $N' \equiv N$. Table 4 gives the nonparametric estimates $\tilde{M}_U(t)$ and $\tilde{M}_T(t)$ (evaluated at the failure times

z_l , $l = 1, 2, \dots, 23$). The estimate $\tilde{M}_T(z_l)$ departs from $\tilde{M}_U(z_l)$ as from $l = 18$, since the time interval $(z_{17}, z_{18}) = (639 \text{ h}, 650 \text{ h})$ includes the censoring time $T_4 = 648 \text{ h}$ of Plane #4 and the operating interval (z_{17}, T_4) without failures of Plane #4 is ignored by $\tilde{M}_U(t)$. A further departure occurs as from $l = 19$, since the time interval $(z_{18}, z_{19}) = (650 \text{ h}, 1253 \text{ h})$ includes the censoring time $T_3 = 800 \text{ h}$ of Plane #3. Note that all these analyses are for illustration purposes only.

Parametric Estimators

Maximum likelihood estimation procedures are provided here for two cases; in the first case, the failure patterns are modeled by identical homogeneous Poisson processes, in the second case an NHPP with power-law intensity (called the *PLP*) is adopted.

Homogeneous Poisson Processes. Suppose that m identical repairable systems are observed up to time T_j ($j = 1, 2, \dots, m$) and that n_j failures are experienced by the j th system. If each failure pattern is modeled by an HPP with common constant intensity λ , the MLE of λ is

$$\hat{\lambda} = \frac{\sum_{j=1}^m n_j}{\sum_{j=1}^m T_j}, \quad (45)$$

that is, it is the ratio of the total number of observed failures, say $N = \sum_{j=1}^m n_j$, over the total operating time of all the systems.

If all processes are failure truncated, so that $T_j \equiv t_{n_j, j}$ ($j = 1, 2, \dots, m$) is a random variable, the quantity $2\lambda / \sum_{j=1}^m T_j$ has a chi-square distribution with $2N$ degrees of freedom, and the equal-tail $(1 - \alpha)$ confidence interval for λ is

$$\left(\frac{\chi_{1-\alpha/2}^2(2N)}{2 \sum_{j=1}^m T_j}, \frac{\chi_{\alpha/2}^2(2N)}{2 \sum_{j=1}^m T_j} \right). \quad (46)$$

according to Ref. 8. The MLE of the mean value function is

$$\hat{M}(t) = t\hat{\lambda} = \frac{Nt}{\sum_{j=1}^m T_j}, \quad (47)$$

and the equal-tail $(1 - \alpha)$ confidence interval for $M(t)$ is

$$\left(\frac{t \cdot \chi_{1-\alpha/2}^2(2N)}{2 \sum_{j=1}^m T_j}, \frac{t \cdot \chi_{\alpha/2}^2(2N)}{2 \sum_{j=1}^m T_j} \right). \quad (48)$$

From Equation (47) we have $\sum_{j=1}^m \hat{M}(T_j) = \hat{M}(\sum_{j=1}^m T_j) = N$, that is, the MLE of the mean value function over the entire observation period equals the total number of observed failures.

If some of the systems are time truncated, so that, for some j 's, $T_j > t_{n_j, j}$, the MLE of λ and $M(t)$ are still given by Equations (45) and (47) respectively. In this case, an approximate $(1 - \alpha)$ confidence interval for λ can be obtained estimating the asymptotic standard deviation of $\hat{\lambda}$ by

$$\hat{\sigma}(\hat{\lambda}) = \sqrt{\left[-\frac{\partial^2 \ell(\lambda)}{\partial \lambda^2} \Big|_{\hat{\lambda}} \right]^{-1}} = \frac{\hat{\lambda}}{\sqrt{N}}, \quad (49)$$

where the second derivative of the log-likelihood function $\ell(\lambda) = N \ln \lambda + \lambda \sum_{j=1}^m T_j$

with respect to λ is to be evaluated at the MLE $\hat{\lambda}$. Then, according to the approximation chosen for the asymptotic distribution of $\hat{\lambda}$, the normal or the log-normal one, the approximate equal-tail $(1 - \alpha)$ confidence intervals for $\lambda(t)$ results in either

$$\hat{\lambda} \pm z_{\alpha/2} \hat{\sigma}(\hat{\lambda}) \quad (50)$$

or

$$\hat{\lambda} \cdot \exp\{\pm z_{\alpha/2} \hat{\sigma}(\hat{\lambda}) / \hat{\lambda}\}. \quad (51)$$

An approximate $(1 - \alpha)$ confidence interval for λ can be also obtained by considering the likelihood ratio test of the null hypothesis $H_0 : \lambda = \lambda_0$ against the alternative hypothesis $H_1 : \lambda \neq \lambda_0$ [8]. Specifically, such a confidence interval for λ consists of all the values of λ_0 for which the null hypothesis is not rejected, that is, all the values of λ_0 for which

the log-likelihood statistic

$$\Lambda(\lambda_0) = -2 \left(N \ln \left[\lambda_0 \cdot \sum_{j=1}^m T_j \right] - N \ln N + N - \lambda_0 \cdot \sum_{j=1}^m T_j \right) \quad (52)$$

is less than the α critical value of the chi-square distribution with one degree of freedom, say $\chi_{\alpha}^2(1)$. In practice, once $\Lambda(\lambda_0)$ has been plotted against λ_0 , the approximate $(1 - \alpha)$ confidence interval for λ is given by all the values of λ_0 for which $\Lambda(\lambda_0) < \chi_{\alpha}^2(1)$ [8].

Once the confidence interval for λ , say $(\lambda_{\alpha/2}, \lambda_{1-\alpha/2})$, has been obtained, an approximate $(1 - \alpha)$ confidence interval for $M(t)$ is given by $(t\lambda_{\alpha/2}, t\lambda_{1-\alpha/2})$.

Example 2 (continued). Let us continue to consider the air-conditioning data of Table 3. By assuming that the

air-conditioning systems operated under identical working conditions, underwent minimal repair at failures, and experienced no trend with operating time, the HPP with intensity λ is used to model their failure process. From Equation (45), the MLE of λ is $\hat{\lambda} = 23/3741 = 0.006148 \text{ h}^{-1}$.

From Equation (49), the estimate of the asymptotic standard deviation of $\hat{\lambda}$ results in $\hat{\sigma}(\hat{\lambda}) = 0.006148/\sqrt{23} = 0.001282 \text{ h}^{-1}$. Choosing the log-normal approximation for the distribution of $\hat{\lambda}$, the approximate 95% confidence interval for λ is $(0.004086 \text{ h}^{-1}, 0.009252 \text{ h}^{-1})$. Alternatively, by using the method based on the log-likelihood statistic (Eq. 52), the approximate 95% confidence limits for λ results in $\lambda_{0.025} = 0.003965 \text{ h}^{-1}$ and $\lambda_{0.975} = 0.009014 \text{ h}^{-1}$.

Power-Law Process. Suppose that m identical repairable systems are observed up to time T_j ($j = 1, 2, \dots, m$) and that n_j failures are experienced by the j th system at times t_{ij} ($i = 1, 2, \dots, n_j$ and $j = 1, 2, \dots, m$). If each failure pattern is modeled by a PLP with common intensity function $\lambda(t) = (\beta/\theta)(t/\theta)^{\beta-1}$, the MLE of parameters are obtained by numerically solving

$$\hat{\beta} = \frac{N}{\sum_{j=1}^m (T_j/\hat{\theta})^{\hat{\beta}} \ln T_j - \sum_{j=1}^m \sum_{i=1}^{n_j} \ln t_{ij}} \text{ and}$$

$$\hat{\theta} = \left(\frac{\sum_{j=1}^m T_j^{\hat{\beta}}}{N} \right)^{1/\hat{\beta}}, \quad (53)$$

where $N = \sum_{j=1}^m n_j$ [12]. The MLE of the intensity function and of the mean value function, at a given time t , result in

$$\hat{\lambda}(t) = \frac{N \hat{\beta} t^{\hat{\beta}-1}}{\sum_{j=1}^m T_j^{\hat{\beta}}} \text{ and } \hat{M}(t) = \frac{N t^{\hat{\beta}}}{\sum_{j=1}^m T_j^{\hat{\beta}}}. \quad (54)$$

From Equation (54), we have $\sum_{j=1}^m \hat{M}(T_j) = N$, that is, the MLE of the mean value function over all the observation periods equals the total number of observed failures.

When $T_1 = T_2 = \dots = T_m = T$, the MLE of $\lambda(t)$ and $M(t)$ result in

$$\hat{\lambda}(t) = \frac{N \hat{\beta} t^{\hat{\beta}-1}}{m T^{\hat{\beta}}} \text{ and } \hat{M}(t) = \frac{N}{m} \left(\frac{t}{T} \right)^{\hat{\beta}}, \quad (55)$$

where $\hat{\beta} = N / \sum_{j=1}^m \sum_{i=1}^{n_j} \ln(T/t_{ij})$ and $\hat{\theta} = T/(N/m)^{1/\hat{\beta}}$.

For equal or unequal censoring times, approximate confidence intervals for $\lambda(t)$ and $M(t)$ can be obtained by applying the Delta method, as illustrated in the section titled "Data from a Single Repairable System" using the first derivatives of $\lambda(t)$ and $M(t)$ given by Equations (22) and (23) respectively, and the estimated covariance matrix $C(\hat{\theta}, \hat{\beta})$.

ESTIMATING SURVIVAL PROBABILITY

MASSIMILIANO GIORGIO

The *survival probability* $R(t)$, often called the *reliability function*, is one of the widely used metrics for reliability of nonrepairable units. It is defined as the probability that a product performs its intended function without failure under specified operating conditions for a given period of time t [1]:

$$R(t) = \Pr(T > t), \quad t \geq 0, \quad (1)$$

where T is a continuous nonnegative random variable denoting the time to failure. Accordingly to definition (1), $R(t)$ is a right continuous nondecreasing function of t .

In addition, the conditional survivor function, that is, the probability that a (not-failed) unit of age t survives to w extra units of time, is given by

$$R(w | t) = \Pr(T - t > w | T > t) = \frac{R(t + w)}{R(t)}, \quad (2)$$

being $T - t$ its residual life.

As definition (1) involves the concept of probability, reliability measurement requires probabilistic and statistical methods. A number of classical nonparametric and parametric procedures for estimating the reliability function $R(t)$ of nonrepairable units from homogeneous samples are here illustrated. Methods for performing analysis in presence of heterogeneity are discussed

in Refs 2–5 and Bayesian approaches are treated in Refs 6 and 7.

RELIABILITY DATA DISTINGUISHING FEATURES

What distinguishes reliability data, or more in general lifetime data, from data used in other field of statistics is the frequent presence of *censoring*. To obtain the exact value of the time to failure of a unit it is necessary to continuously monitor the unit all through its life. Typically lifetime samples are incomplete or censored. In fact, very frequently, the lifetime is exactly known only for a portion of the units under study, whereas only incomplete information is available about the failure time of the others. Censoring arises in various ways and many different kinds of censored sampling are considered in literature [2,3,8]. The case of right censored observations is specifically addressed in the following. In general, a sample is called *singly censored* if all the survivors have the same censoring time, whereas it is called *multiply censored* if survivors have different censoring times.

Only standard methods for censored data analysis are presented in this article. The use of these methods requests the assumption that censoring mechanisms are noninformative (or *independent*), that is, the censoring time does not give information about the failure time distribution [9].

NONPARAMETRIC PROCEDURES

Complete and Singly Right Censored Samples

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ denote a complete sample of n data from a single distribution function, and let $\mathbf{x} = \{x_{(1)}, \dots, x_{(h)}\}$ indicate the ordered set of the h distinct values of set $\mathbf{t}$ ($h \leq n$) at which one or more failures occur. From definition (1), a natural nonparametric estimator of the reliability function $R(t)$ at the time t is given by the fraction of units survived beyond t , say:

$$\tilde{R}(t) = \begin{cases} 1, & \text{for } 0 \leq t < x_{(1)} \\ 1 - \sum_{j=1}^i d_j/n, & \text{for } x_{(i)} \leq t < x_{(i+1)}, \\ & i = 1, 2, \dots, h-1, \\ 0, & \text{for } t \geq x_{(h)} \end{cases} \quad (3)$$

where $x_{(0)} \equiv 0$, d_j is the number of units failed at $x_{(j)}$ and $n - \sum_{j=1}^i d_j$ is the number of units that survive time $x_{(j)}$. $\tilde{R}(t)$ is a staircase function, that is, it is flat between successive failure times.

In the case of singly censored sample data, the same approach can be adopted. The main feature of singly right censored sample data is that all failure times are smaller than or equal to the unique single censoring time, say $T_C \geq x_{(h)}$. In this case,

$$\tilde{R}(t) = \begin{cases} 1, & \text{for } 0 \leq t < x_{(1)} \\ 1 - \sum_{j=1}^i d_j/n, & \text{for } x_{(i)} \leq t < x_{(i+1)}, \\ & i = 1, 2, \dots, h-1, \\ 1 - \sum_{j=1}^h d_j/n, & \text{for } x_{(h)} \leq t \leq T_C \end{cases} \quad (4)$$

where $\sum_{j=1}^h d_j$ is the total number of failed items in the sample. Estimator (4) can be used also in the case of multiply censored samples, provided that all failure times are not greater than the smallest censoring time. In this case, T_C equals the largest censoring time.

In the case of complete or singly censored samples, the exact $(1 - \alpha)$ confidence interval, say $(\tilde{R}_L(t), \tilde{R}_U(t))$, can be obtained by solving the following binomial-based equations [10]:

$$\begin{aligned} \tilde{R}_L(t) &: \sum_{j=0}^{n\tilde{R}(t)-1} \binom{n}{j} (\tilde{R}_L(t))^j (1 - \tilde{R}_L(t))^{n-j} \\ &= 1 - \alpha/2 \end{aligned}$$

$$\begin{aligned} \tilde{R}_U(t) &: \sum_{j=0}^{n\tilde{R}(t)} \binom{n}{j} (\tilde{R}_U(t))^j (1 - \tilde{R}_U(t))^{n-j} \\ &= \alpha/2. \end{aligned} \quad (5)$$

Of course, in case of censoring, the time axis can be investigated up to the censoring time, say $x_{(h)}$ or T_C . Exploiting the relationship between the cumulative binomial function and the cumulative beta distribution, the limits (Eq. 5) can be obtained by inverting the cumulative beta distribution, so that

$$\begin{aligned} \tilde{R}_L(t) &= B_{\alpha/2}(n\tilde{R}, n(1 - \tilde{R}) + 1) \quad \text{and} \\ \tilde{R}_U(t) &= B_{1-\alpha/2}(n\tilde{R} + 1, n(1 - \tilde{R})), \end{aligned} \quad (6)$$

where $B_\gamma(p, q)$ denotes the γ th quantile of the beta distribution with parameters p and q , and $\tilde{R}$ stands for $\tilde{R}(t)$. Alternatively, a conservative $(1 - \alpha)$ confidence interval for the reliability $R(t)$, at any specified time t not greater than the censoring time, is given by Blyth [11]:

$$\begin{aligned} \tilde{R}_L(t) &= \left[1 + \frac{[n(1 - \tilde{R}) + 1]F_{1-\alpha/2}(2n(1 - \tilde{R}) + 2, 2n\tilde{R})}{n\tilde{R}} \right]^{-1} \\ \tilde{R}_U(t) &= \left[1 + \frac{n(1 - \tilde{R})}{(n\tilde{R} + 1)F_{1-\alpha/2}(2n\tilde{R} + 2, 2n(1 - \tilde{R}))} \right]^{-1}, \end{aligned} \quad (7)$$

where $F_\gamma(v_1, v_2)$ is the γ th quantile of the F distribution with v_1 and v_2 degrees of freedom.

Approximate $(1 - \alpha)$ confidence intervals can be also constructed by using the method recommended by Ref. 12:

$$\begin{aligned} \tilde{R}_L(t) &= \frac{\tilde{R} + z_{\alpha/2}^2/(2n) + z_{\alpha/2}\sqrt{\tilde{R}(1 - \tilde{R})/n - z_{\alpha/2}^3/(4n^2)}}{1 + z_{\alpha/2}^2/n} \\ \tilde{R}_U(t) &= \frac{\tilde{R} + z_{\alpha/2}^2/(2n) - z_{\alpha/2}\sqrt{\tilde{R}(1 - \tilde{R})/n - z_{\alpha/2}^3/(4n^2)}}{1 + z_{\alpha/2}^2/n}, \end{aligned} \quad (8)$$

where $z_{\alpha/2}$ is the $(\alpha/2)$ th quantile of the standard normal distribution. This approach is substantiated on the grounds that it is the exact algebraic counterpart of the large-sample hypothesis test. It is also supported by investigations of Agresti and Coull [12]. One advantage of this method is that its worth does not strongly depend upon the value of n and/or $\tilde{R}$, and is recommended for virtually all combinations of n and/or $\tilde{R}$. Another advantage of this method is that the lower limit cannot be negative, although the upper limit can be sometimes larger than 1 for large $\tilde{R}$ and small n values.

As a further alternative, and perhaps the most frequently used, the normal approximation can be adopted:

$$\begin{aligned} \tilde{R}_L(t) &= \tilde{R}(t) + z_{\alpha/2} \tilde{\sigma}_{\tilde{R}} \\ \text{and } \tilde{R}_U(t) &= \tilde{R}(t) - z_{\alpha/2} \tilde{\sigma}_{\tilde{R}}, \end{aligned} \quad (9)$$

where

$$\tilde{\sigma}_{\tilde{R}} = \sqrt{\tilde{R}(1 - \tilde{R})/n} \quad (10)$$

is an estimate of the standard deviation of $\tilde{R}(t)$. For the normal approximation to not be poor, both the inequalities $n\tilde{R} \geq 5$ and $n(1 - \tilde{R}) \geq 5$ should be satisfied.

For small n values, better results are generally obtained if the normal approximation for $\text{logit}(\tilde{R}(t)) = \ln[(1 - \tilde{R}(t)) / \tilde{R}(t)]$ is used, which gives the following $(1 - \alpha)$ confidence interval [5]:

$$\tilde{R}_L(t) = \frac{\tilde{R}}{\tilde{R} + (1 - \tilde{R}) \times w_{\alpha/2}(\tilde{R})}$$

and

$$\tilde{R}_U(t) = \frac{\tilde{R}}{\tilde{R} + (1 - \tilde{R})/w_{\alpha/2}(\tilde{R})}, \quad (11)$$

where $w_{\alpha/2}(\tilde{R}) = \exp\{-z_{\alpha/2} \tilde{\sigma}_{\tilde{R}} / [\tilde{R}(1 - \tilde{R})]\}$. If the standard deviation $\sigma_{\tilde{R}}$ is estimated through Equation (10), we have that $w_{\alpha/2}(\tilde{R}) = \exp\{-z_{\alpha/2} / \sqrt{n\tilde{R}(1 - \tilde{R})}\}$. The interval in Equation (11), different from the interval in Equation (9), surely satisfies the constraints $0 \leq \tilde{R}_L(t), \tilde{R}_U(t) \leq 1$.

All the above-mentioned procedures for constructing confidence intervals for $R(t)$ can also be used in the case of multiply censored samples, provided that censoring times are equal to or greater than the largest failure time $x_{(h)}$. In this case, the time axis can be investigated until the largest censoring time.

Example 1. Let us consider the Type I censored data given in Ref. 13, which refers to 15 units of an electromechanical module tested at the temperature of 125°C. All the tests were stopped at the time $T_C = 1100$ h and eight failures were observed at no tied times, which, once ordered, are

$$\begin{aligned} x_{(1)} &= 88 \text{ h}, & x_{(2)} &= 105 \text{ h}, & x_{(3)} &= 141 \text{ h}, \\ x_{(4)} &= 344 \text{ h}, & x_{(5)} &= 430 \text{ h}, & x_{(6)} &= 516 \text{ h}, \\ x_{(7)} &= 937 \text{ h}, & x_{(8)} &= 1057 \text{ h}. \end{aligned}$$

The nonparametric estimate (4) of the reliability in each time interval $[x_{(i-1)}, x_{(i)}]$ is given in Table 1 and depicted in Fig. 1. Exact confidence intervals for the reliability at any fixed time $t \leq T_C$ are obtained from Equation (6). For example, for $t = 250$ h, the exact 95% confidence interval is

$$\tilde{R}_L(250) = 0.519 \quad \text{and} \quad \tilde{R}_U(250) = 0.957.$$

By using Equation (7), a conservative 95% confidence interval for the reliability at time $t = 250$ h is

Table 1. Nonparametric Estimate of the Reliability Function in Each Time Interval $[x_{(i-1)}, x_{(i)}]$, $i = 1, 2, \dots, 9$, for Example 1

i	$[x_{(i-1)}, x_{(i)}]$	$\tilde{R}(t)$
1	[0, 88)	1.000
2	[88, 105)	0.933
3	[105, 141)	0.867
4	[141, 344)	0.800
5	[344, 430)	0.733
6	[430, 516)	0.667
7	[516, 937)	0.600
8	[937, 1057)	0.533
9	[937, 1100]	0.467

Figure 1. Plot of the nonparametric estimate $\tilde{R}(t)$ of the reliability function in Example 1.

$$\tilde{R}_L(250) = \left[1 + \frac{(15 \times 0.200 + 1) \times 2.779}{15 \times 0.800} \right]^{-1} = 0.519$$

and

$$\tilde{R}_U(250) = \left[1 + \frac{15 \times 0.200}{(15 \times 0.800 + 1) \times 5.097} \right]^{-1} = 0.957,$$

being $F_{1-\alpha/2}(2n(1-\tilde{R})+2, 2n\tilde{R}) = F_{0.975}(8, 24) = 2.779$ and $F_{1-\alpha/2}(2n\tilde{R}+2, 2n(1-\tilde{R})) = F_{0.975}(26, 6) = 5.097$. The normal approximate confidence interval (Eq. 9) provides:

$$\tilde{R}_L(250) = 0.800 + z_{0.025} \sqrt{\frac{0.800(1-0.800)}{15}} = 0.598$$

and

$$\tilde{R}_U(250) = 0.800 - z_{0.025} \sqrt{\frac{0.800(1-0.800)}{15}} = 1.002,$$

which, however, gives an upper limit $\tilde{R}_U(250)$ greater than 1, that is outside the possible range of values for $R(t)$. Thus, $\tilde{R}_U(250) = 1$ must be adopted. This undesirable result is due to the fact that the normal approximation here is poor for $t = 250$ h because, for $n = 15$ and $\tilde{R}(250) = 0.800$, the conditions $n\tilde{R}(250) \geq 5$ and $n[1-\tilde{R}(250)] \geq 5$ are not both satisfied, being $n[1-\tilde{R}(250)] = 3$. Finally, the approximate confidence interval

(Eq. 11) based on the logit transformations are

$$\begin{aligned} \tilde{R}_L(250) &= \frac{\tilde{R}}{\tilde{R} + (1-\tilde{R}) \times w_{0.975}(\tilde{R})} \\ &= \frac{0.800}{0.800 + (1-0.800) \times 3.544} \\ &= 0.530 \end{aligned}$$

and

$$\begin{aligned} \tilde{R}_U(250) &= \frac{0.800}{0.800 + (1-0.800)/3.544} \\ &= 0.934, \end{aligned}$$

where

$$\begin{aligned} w_{0.025}(\tilde{R}) &= \exp\{1.960/\sqrt{15 \cdot 0.800(1-0.800)}\} \\ &= 3.544. \end{aligned}$$

Multiply Censored Samples with Intermixed Failure and Censoring Times

Multiply censored samples are usually characterized by the fact that failure and censoring times are intermixed. In this case, the nonparametric estimation procedure (Eq. 4) cannot be applied and *ad hoc* methods must be used; among them, one of the most widely used is the Kaplan–Meier, or *product limit*, estimation method [1].

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ denote a random sample of size n consisting of r failure times and $n-r$ censored observations, and let $\mathbf{x} = \{x_{(1)}, x_{(2)}, \dots, x_{(h)}\}$ denote the ordered

set of the h ($h \leq r$) distinct times at which one or more failures occur. Moreover, let d_i ($i = 1, 2, \dots, h$) denote the number of failures that occurred at the same time $x_{(i)}$ ($\sum_{i=1}^h d_i = r$), let C_i denote the total number of censorings that occurred before time $x_{(i)}$, and let k_i indicate the number of units at risk (neither failed nor withdrawn) immediately before $x_{(i)}$; $k_1 = n - C_1$ and

$$k_i = n - \sum_{j=1}^{i-1} d_j - C_i, \quad i = 2, \dots, h. \quad (12)$$

In the case of a tie between a censoring time and the generic failure time $x_{(i)}$, the Kaplan–Meier method assumes that the censoring time is infinitesimally larger than $x_{(i)}$, so that the censored unit is still at risk at $x_{(i)}$. Under this assumption, the Kaplan–Meier estimate of the reliability function is

$$\begin{aligned} \bar{R}(t) &= \begin{cases} 1, & 0 \leq t < x_{(1)} \\ \prod_{j=1}^i \frac{k_j - d_j}{k_j}, & x_{(i)} \leq t < x_{(i+1)}, \\ & i = 1, \dots, h-1, \\ \prod_{j=1}^h \frac{k_j - d_j}{k_j}, & x_{(h)} \leq t \leq t_{\max} \end{cases} \quad (13) \end{aligned}$$

where $t_{\max}$ is the largest value in $\{t_1, t_2, \dots, t_n\}$.

In presence of multiply censoring with intermixed failure and censoring times, an estimate of the standard deviation $\sigma_{\bar{R}}$ of $\bar{R}(t)$ may be obtained via the Greenwood's formula [2]:

$$\sigma_{\bar{R}} = \bar{R}(t) \sqrt{\sum_{j: x_{(j)} \leq t} \frac{d_j}{k_j(k_j - d_j)}}, \quad (14)$$

and approximate confidence intervals for $\bar{R}(t)$, at any fixed time $t \leq t_{\max}$, can be obtained through Equations (9) or (11), by using $\bar{R}$ and Equation (14) instead of $\tilde{R}$ and Equation (10), respectively. Note that, when there are no censored observations before a given time t , Equation (14) is numerically equal to Equation (10) up to that t value.

For large samples, suitable alternatives to the Kaplan–Meier estimator (13) are

the *actuarial* estimators, which are usually adopted to face situations in which the exact time to failure or the censoring time of some units is not available: it is only known that failure or censoring occurred after a some time point and before a later time point (i.e., interval-censored data). Nevertheless, especially in the case of large sample size, the actuarial estimators are often used also when the exact failure times are known in order to gain computational advantage (i.e., grouping of data is time saving). To perform the actuarial estimate, the whole interval $(0, t_{\max})$ has to be partitioned into a number m of subintervals, say $(\tau_{i-1}, \tau_i]$ ($i = 1, 2, \dots, m$), being $\tau_0 \equiv 0$ and $\tau_m = t_{\max}$. These subintervals may be of equal length, but this is not necessary. They only have to be contiguous.

Let c_i and d_i indicate, respectively, the number of units withdrawn from the test during the i th subinterval $(\tau_{i-1}, \tau_i]$ and the number of failures that occurred in $(\tau_{i-1}, \tau_i]$. Then, the number k_i ($i = 1, 2, \dots, m$) of units at risk at the beginning of the i th subinterval $(\tau_{i-1}, \tau_i]$ is $k_1 \equiv n$ and

$$k_i = n - \left(\sum_{j=1}^{i-1} d_j + \sum_{j=1}^{i-1} c_j \right), \quad i = 2, \dots, m.$$

Within such a notation, the *simple* actuarial estimate of the reliability function is

$$\tilde{R}_S(\tau_i) = \prod_{j=1}^i \left(1 - \frac{d_j}{k_j} \right), \quad i = 1, 2, \dots, m. \quad (15)$$

In order to take into account that the c_j units withdrawn from the test during the subinterval $(\tau_{j-1}, \tau_j]$ remain at risk only for a part of this subinterval, the *adjusted* actuarial estimator can be used [1]:

$$\tilde{R}_A(\tau_i) = \prod_{j=1}^i \left(1 - \frac{d_j}{k_j - c_j/2} \right), \quad i = 1, 2, \dots, m, \quad (16)$$

where the adjustment factor $-c_j/2$ arises from the assumption that c_j units run about half the subinterval $(\tau_{j-1}, \tau_j]$. Other

Table 2. Failure and Censoring Data of Diesel Generator Fans in Example 2

i	$x_{(i)}$	d_i	C_i	k_i

censoring adjustments have been proposed in the literature [14].

In contrast to the Kaplan–Meier estimator, the actuarial estimators give reliability estimates at the endpoints of the subintervals. If the i th subinterval contains one or more failures, then $\tilde{R}_S(t)$ and $\tilde{R}_A(t)$ are to be considered undefined within this subinterval. If no failure occurs in (τ_{i-1}, τ_i) , then $\tilde{R}_S(t) = \tilde{R}_S(\tau_{i-1})$ and $\tilde{R}_A(t) = \tilde{R}_A(\tau_{i-1})$ for any $\tau_{i-1} \leq t < \tau_i$. As the lengths of the subintervals approach zero, the simple actuarial estimator (15) and the Kaplan–Meier estimator (13) coincide.

As in the case of the Kaplan–Meier estimator, confidence intervals for $R(t)$ can be computed through Equations (9) or (11). The Greenwood’s formula (14) is used to estimate the standard deviation of $\tilde{R}_S(t)$ or $\tilde{R}_A(t)$, where $k_j - c_j/2$ ($j = 1, 2, \dots, m$) should be used instead of k_j for estimating $\tilde{\sigma}_{\tilde{R}_A}$, so that

$$\tilde{\sigma}_{\tilde{R}_S} = \tilde{R}_S(\tau_i) \sqrt{\sum_{j=1}^i \frac{d_j}{k_j(k_j - d_j)}}$$

and

$$\tilde{\sigma}_{\tilde{R}_A} = \tilde{R}_A(\tau_i) \sqrt{\sum_{j=1}^i \frac{d_j}{(k_j - c_j/2)(k_j - c_j/2 - d_j)}}. \quad (17)$$

Example 2. Let us consider the data of $n = 70$ fans of diesel generators given by

Ref. 1. These data consist of the $r = 12$ failure times (in hours) of the failed fans and of the $n - r = 58$ running times (in hours) of the unfailed fans. The largest time is a censoring time, equal to $t_{\max} = 11,500$ h. Table 2 gives the distinct (ordered) times $x_{(i)}$ ($i = 1, 2, \dots, 10$) at which failures occurred (two pairs of failure times are recorded as equal), together with the number d_i of fans failed at $x_{(i)}$, the total number C_i of fans censored before $x_{(i)}$, and the number k_i of fans at risk immediately before $x_{(i)}$. Table 3 gives the Kaplan–Meier estimate (13) of the reliability function for each time interval between two successive failure times, together with the standard deviation $\bar{\sigma}_{\bar{R}}$ estimated from Equation (14). In Fig. 2 the reliability estimate $\bar{R}(t)$ is also depicted.

Approximate 90% confidence intervals for the reliability function at any time $t \leq t_{\max} = 11,500$ h are given in Table 3 by using the normal approximation of Equation (9) or the logit transformation of Equation (11). For example, at $t = 3800$ h, the normal approximation provides

$$\begin{aligned} \bar{R}_L(3800) &= \bar{R}(3800) + z_{0.05} \times \bar{\sigma}_{\bar{R}(3800)} \\ &= 0.852 - 1.645 \times 0.0460 \\ &= 0.777 \end{aligned}$$

and

$$\begin{aligned} \bar{R}_U(3800) &= \bar{R}(3800) - z_{0.05} \times \bar{\sigma}_{\bar{R}(3800)} \\ &= 0.852 + 1.645 \times 0.0460 = 0.928, \end{aligned}$$

being $\bar{R}(3800) = 0.852$ and $\bar{\sigma}_{\bar{R}(3800)} = 0.0460$, whereas the logit transformation gives:

$$\begin{aligned} \bar{R}_L(3800) &= \frac{\bar{R}(3800)}{\bar{R}(3800) + (1 - \bar{R}(3800)) \times w_{0.05}(\bar{R})} \\ &= \frac{0.852}{0.852 + 0.148 \times 1.823} = 0.760 \end{aligned}$$

and

$$\begin{aligned} \bar{R}_U(3800) &= \frac{\bar{R}(3800)}{\bar{R}(3800) + (1 - \bar{R}(3800))/w_{0.05}(\bar{R})} \\ &= 0.913, \end{aligned}$$

Table 3. Kaplan–Meier Estimate $\bar{R}(t)$ of the Reliability Function, Estimate of its Standard Deviation $\sigma_{\bar{R}}$, and Approximate 90% Confidence Intervals for the Data in Example 2

**Figure 2.** Plot of the Kaplan–Meier estimate $\bar{R}(t)$ of the reliability function in Example 2.

where $w_{0.05}(\bar{R}) = \exp[1.645 \times 0.046 / (0.852 \times 0.148)] = 1.823$. Note that, for $450 \text{ h} \leq t < 1150 \text{ h}$, the normal approximation provides an upper limit for $R(t)$ greater than 1, and then the value $\bar{R}_L(t) = 1$ must be assumed here.

PARAMETRIC PROCEDURES

Parametric estimation procedures request that a probability model is assumed for the failure time distribution, say

$$T \sim f(t; \theta), \quad t \geq 0,$$

where $\theta = \{\theta_1, \theta_2, \dots, \theta_l\}$ is the vector of l model parameters, some of which are

unknown. Among all the parametric estimation procedures, only the maximum likelihood (ML) estimation method is here discussed, and the specific cases of the exponential and Weibull distributions are considered in detail.

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ denote a random sample of size n of exact failure times and right censored data from the failure time distribution $f(t; \theta)$. The idea behind ML estimation is that the value of model parameters, which maximizes the probability (likelihood) of the sample data, is their best estimate. In this context, the (joint) data probability function is called the *likelihood function*, say $L(\theta; \mathbf{t})$, to highlight that it is regarded as a function of the unknown parameters. Since

multiplying the joint distribution function by a constant does not alter the ML estimates, the likelihood function is usually defined up to a *constant* multiplicative factor (where the term *constant* is used to mean that it does not depend on the unknown parameters, even if it may possibly depend on the data). Under such hypotheses, the likelihood function $L(\boldsymbol{\theta}; \mathbf{t})$ is

$$L(\boldsymbol{\theta}; \mathbf{t}) = \prod_{i=1}^n f(t_i; \boldsymbol{\theta})^{\delta_i} R(t_i; \boldsymbol{\theta})^{1-\delta_i}, \quad (18)$$

where $\delta_i = 1$ if t_i is an exact failure time, and $\delta_i = 0$ if t_i is a right censored observation.

The ML estimate of $\boldsymbol{\theta}$, say $\hat{\boldsymbol{\theta}} = \{\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_l\}$, can be obtained (if it exists) as

$$\hat{\boldsymbol{\theta}} = \max_{\boldsymbol{\theta} \in \Theta} L(\boldsymbol{\theta}; \mathbf{t}),$$

being Θ the space of the parameters. Then, the ML estimate of the reliability function at any time $t \geq 0$ can be easily obtained as

$$\hat{R}(t) = R(t; \hat{\boldsymbol{\theta}}). \quad (19)$$

If an analytic closed form expression exists for $R(t)$, it is generally possible to reparameterize the distribution function so that the reliability value $R_x = R(x)$ at whatever prefixed time x explicitly appears as a parameter of the probability model (see section titled “Data from the Two-Parameter Weibull Distribution”). In this case, the direct estimation of $R_x = R(x)$ can be performed. Owing to the invariance property of the ML method, such an estimate will coincide with the indirect estimate (19).

In performing the ML estimate, it is generally much more convenient to work with the log-likelihood function:

$$\begin{aligned} \ell(\boldsymbol{\theta}; \mathbf{t}) &= \ln L(\boldsymbol{\theta}; \mathbf{t}) = \sum_{i=1}^n [\delta_i \ln f(t_i; \boldsymbol{\theta}) \\ &\quad + (1 - \delta_i) \ln R(t_i; \boldsymbol{\theta})]. \end{aligned} \quad (20)$$

Indeed, since the logarithm function is a monotone increasing function, the value $\hat{\boldsymbol{\theta}}$ that maximizes $\ell(\boldsymbol{\theta}; \mathbf{t})$, if it exists, is the same that maximizes $L(\boldsymbol{\theta}; \mathbf{t})$. The advantage in maximizing the log-likelihood function is

that the logarithmic transformation usually yields simplified mathematics, since it transforms products in sums. Moreover, it often prevents such computational problems as overflows and/or underflows, often caused by Equation (18).

Approximate confidence intervals for $R(t)$, homolog to the confidence intervals (Eq. 9) for nonparametric estimates, can be obtained adopting the normal approximation for the distribution of $\hat{R}(t)$, so that

$$\hat{R}_L(t) = \hat{R}(t) + z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{R}(t))}$$

and

$$\hat{R}_U(t) = \hat{R}(t) - z_{\alpha/2} \sqrt{\hat{\text{Var}}(\hat{R}(t))}, \quad (21)$$

where $z_{\alpha/2}$ is the $\alpha/2$ th quantile of the standard normal distribution and $\hat{\text{Var}}(\hat{R}(t))$ denotes the estimate of the asymptotic variance of $\hat{R}(t)$. Such a variance can be estimated through the delta method [15]:

$$\begin{aligned} \hat{\text{Var}}(\hat{R}(t)) &= \sum_{i=1}^l \left[\frac{\partial R(t)}{\partial \theta_i} \Big|_{\hat{\boldsymbol{\theta}}} \right]^2 \hat{\text{Var}}(\hat{\theta}_i) + 2 \sum_{i=1}^l \sum_{j=i+1}^l \\ &\quad \times \frac{\partial R(t)}{\partial \theta_i} \Big|_{\hat{\boldsymbol{\theta}}} \frac{\partial R(t)}{\partial \theta_j} \Big|_{\hat{\boldsymbol{\theta}}} \hat{\text{Cov}}(\hat{\theta}_i, \hat{\theta}_j), \end{aligned} \quad (22)$$

where $\hat{\text{Var}}(\hat{\theta}_i)$ and $\hat{\text{Cov}}(\hat{\theta}_i, \hat{\theta}_j)$ ($i, j = 1, \dots, l$) are the elements (i, i) and (i, j) , respectively, of the estimated asymptotic variance-covariance matrix $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ of the parameter vector $\boldsymbol{\theta}$ (see section titled “Appendix”), and the partial derivatives of $R(t)$ with respect to the model parameters must be evaluated at the ML estimate $\hat{\boldsymbol{\theta}} = \{\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_l\}$.

Alternative to the normal approximation Equation (21), which does not work well for small and moderate samples, confidence limits based on the logit transformation can be evaluated:

$$\begin{aligned} \hat{R}_L(t) &= \frac{\hat{R}}{\hat{R} + (1 - \hat{R}) \times w_{\alpha/2}(\hat{R})} \quad \text{and} \\ \hat{R}_U(t) &= \frac{\hat{R}}{\hat{R} + (1 - \hat{R})/w_{\alpha/2}(\hat{R})}, \end{aligned} \quad (23)$$

where

$$w_{\alpha/2}(\hat{R}) = \exp \left[-z_{\alpha/2} \frac{\sqrt{\hat{\text{Var}}(\hat{R}(t))}}{\hat{R}(t)(1 - \hat{R}(t))} \right], \quad (24)$$

which assures, unlike Equation (21), that the constraints $0 \leq \hat{R}_L(t), \hat{R}_U(t) \leq 1$ are satisfied for any $t > 0$, even for small samples.

Note that, if the log-likelihood function can be reparameterized in terms of the reliability value $R_x = R(x)$ at the specific time x of interest and in terms of the $(l - 1)$ remaining parameters, say $\{\theta_1, \dots, \theta_{k-1}, \theta_{k+1}, \dots, \theta_l\}$, then $R(x)$ becomes one of the model parameters, say $R(x) \equiv \theta_k$, and the estimated variance of $\hat{R}(x)$ is just the element (k, k) of the matrix $\hat{\mathbf{V}}(\hat{\theta})$.

Also the approximate confidence interval (Eq. 23) can work bad for small samples. More accurate approximate confidence intervals can be obtained adopting the likelihood ratio or a simulation based approach [5]. Moreover, exact solutions for the interval estimation problem are sometimes available, depending on the lifetime distribution model and the censoring scheme. In the following, some procedures for the one-parameter (or standard) exponential and two-parameter Weibull distributions are presented.

Data from the One-Parameter Exponential Distribution

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ be a random sample of size n consisting of exact failure and right censored data from a one-parameter exponential random variable with density function:

$$f(t; \lambda) = \lambda \exp(-\lambda t), \quad \lambda > 0, t \geq 0, \quad (25)$$

and reliability function:

$$R(t; \lambda) = \exp(-\lambda t), \quad \lambda > 0, t \geq 0. \quad (26)$$

The likelihood function $L(\lambda; \mathbf{t})$ relative to such a sample is

$$L(\lambda; \mathbf{t}) \propto \prod_{i=1}^n \lambda^{\delta_i} \exp(-\lambda \delta_i t_i) \times \exp[-\lambda(1 - \delta_i)t_i]$$

$$\begin{aligned} &= \prod_{i=1}^n \lambda^{\delta_i} \exp(-\lambda t_i) \\ &= \lambda^r \exp \left(-\lambda \sum_{i=1}^n t_i \right), \end{aligned}$$

where $\delta_i = 1$ if t_i is an exact failure time, and $\delta_i = 0$ if t_i is a right censored observation. Thus, $\sum_{i=1}^n \delta_i = r$ is the number of exact failure times and the sum $\sum_{i=1}^n t_i$ is the total time on test. The log-likelihood function $\ell(\lambda; \mathbf{t})$ is

$$\begin{aligned} \ell(\lambda; \mathbf{t}) &= \ln \left[\lambda^r \exp \left(-\lambda \sum_{i=1}^n t_i \right) \right] \\ &= r \ln \lambda - \lambda \sum_{i=1}^n t_i, \end{aligned}$$

and, for $r > 0$, the ML estimate of the parameter λ (which represents the constant hazard rate) is equal to the number of observed failures over the total time on test [2]:

$$\hat{\lambda} = \frac{r}{\sum_{i=1}^n t_i}. \quad (27)$$

The ML estimate of the reliability function $R(t; \lambda)$ can be straightforwardly obtained as

$$\begin{aligned} \hat{R}(t) &= R(t; \hat{\lambda}) = \exp(-\hat{\lambda} t) \\ &= \exp \left(-\frac{rt}{\sum_{i=1}^n t_i} \right), \quad t \geq 0. \end{aligned} \quad (28)$$

In the case of complete or Type II censored sample, the exact $(1 - \alpha)$ confidence interval for λ is given by Balakrishnan and Basu [16]:

$$(\hat{\lambda}_L, \hat{\lambda}_U) = \left(\frac{\hat{\lambda} \chi_{\alpha/2}^2(2r)}{2r}, \frac{\hat{\lambda} \chi_{1-\alpha/2}^2(2r)}{2r} \right), \quad (29)$$

where $\chi_{\gamma}^2(\nu)$ is the γ th quantile of the chi-square distribution with ν degrees of freedom. Since, for any fixed $t > 0$, $R(t)$ is a

decreasing function of λ , the exact $(1 - \alpha)$ confidence interval for $R(t)$ is

$$\begin{aligned} & (\hat{R}_L(t), \hat{R}_U(t)) \\ &= (\exp(-\hat{\lambda}_U t), \exp(-\hat{\lambda}_L t)) \\ &= \left(\exp \left[-\frac{t \chi_{1-\alpha/2}^2(2r)}{2 \sum_{i=1}^n t_i} \right], \exp \left[-\frac{t \chi_{\alpha/2}^2(2r)}{2 \sum_{i=1}^n t_i} \right] \right). \end{aligned} \quad (30)$$

In the case of singly Type I or multiply censored samples, exact confidence intervals for $R(t)$ are not available [17]. An approximate $(1 - \alpha)$ confidence interval for λ can be obtained by employing the asymptotic normal approximation of $(\hat{\lambda} - \lambda)/\hat{\sigma}_{\hat{\lambda}}$, where $\hat{\sigma}_{\hat{\lambda}} = \hat{\lambda}/\sqrt{r}$ is the estimated asymptotic standard deviation of $\hat{\lambda}$. Under such an approximation, we have [2]:

$$(\hat{\lambda}_L, \hat{\lambda}_U) = (\hat{\lambda} + z_{\alpha/2} \hat{\lambda}/\sqrt{r}, \hat{\lambda} - z_{\alpha/2} \hat{\lambda}/\sqrt{r}). \quad (31)$$

The approximation (31) works well for moderate and large samples, whereas for small samples a better approximation is given by Sprott [18]:

$$\begin{aligned} & (\hat{\lambda}_L, \hat{\lambda}_U) = \\ & \left(\left[\hat{\lambda}^{1/3} + z_{\alpha/2} \frac{\hat{\lambda}^{1/3}}{3\sqrt{r}} \right]^3, \left[\hat{\lambda}^{1/3} - z_{\alpha/2} \frac{\hat{\lambda}^{1/3}}{3\sqrt{r}} \right]^3 \right), \end{aligned} \quad (32)$$

which employs the normal approximation of $\hat{\lambda}^{1/3}$ in small samples. Another approximate method (often attributed to Ref. 19), which works well in the case of singly Type I censored, treats $2r\lambda/\hat{\lambda}$ as being approximately distributed as a chi-square random variable with $(2r + 1)$ degrees of freedom, so that

$$(\hat{\lambda}_L, \hat{\lambda}_U) = \left(\frac{\hat{\lambda} \chi_{\alpha/2}^2(2r + 1)}{2r}, \frac{\hat{\lambda} \chi_{1-\alpha/2}^2(2r + 1)}{2r} \right). \quad (33)$$

Once an approximate $(1 - \alpha)$ confidence interval for λ has been computed, then

irrespective of the chosen approximation, the approximate $(1 - \alpha)$ confidence interval for $R(t)$ is given by

$$(\hat{R}_L(t), \hat{R}_U(t)) = (\exp(-\hat{\lambda}_U t), \exp(-\hat{\lambda}_L t)). \quad (34)$$

Alternatively, approximate confidence limits based on the logit transformation can be evaluated from Equation (23), where the approximate estimated variance of $\hat{R}(t)$ is

$$\hat{\text{Var}}(\hat{R}(t)) = \left[\frac{dR(t)}{d\lambda} \Big|_{\hat{\lambda}} \right]^2 \hat{\sigma}_{\hat{\lambda}}^2 = \frac{(\hat{\lambda} t)^2 \exp(-2\hat{\lambda} t)}{r}. \quad (35)$$

Example 1 (continued). Let us assume that the electromechanical module data follow the one-parameter exponential function [13]. From Equation (27), the ML estimate of λ is $\hat{\lambda} = 0.000707\text{h}^{-1}$, since the number r of exact failure times is equal to 8 and the total time on test is equal to $\sum_{i=1}^{15} t_i = 11,318\text{h}$. The ML estimate of the reliability at time $t = 250\text{h}$ is

$$\begin{aligned} \hat{R}(250) &= \exp \left(-\frac{rt}{\sum_{i=1}^n t_i} \right) \\ &= \exp \left(-\frac{8 \cdot 250}{11318} \right) = 0.838. \end{aligned} \quad (36)$$

From Equations (31)–(33), approximate 95% confidence intervals for λ result in

$$\begin{aligned} & (\hat{\lambda} + z_{0.025} \hat{\lambda}/\sqrt{r}, \hat{\lambda} - z_{0.025} \hat{\lambda}/\sqrt{r}) \\ &= (0.000217\text{h}^{-1}, 0.001197\text{h}^{-1}), \end{aligned}$$

$$\begin{aligned} & \left(\left[\hat{\lambda}^{1/3} + z_{0.025} \frac{\hat{\lambda}^{1/3}}{3\sqrt{r}} \right]^3, \left[\hat{\lambda}^{1/3} - z_{0.025} \frac{\hat{\lambda}^{1/3}}{3\sqrt{r}} \right]^3 \right) \\ &= (0.000321\text{h}^{-1}, 0.001318\text{h}^{-1}), \end{aligned}$$

$$\left(\frac{\hat{\lambda} \cdot \chi_{0.025}^2(2r+1)}{2r}, \frac{\hat{\lambda} \cdot \chi_{0.975}^2(2r+1)}{2r} \right) \\ = (0.000334h^{-1}, 0.001334h^{-1}),$$

$$(\hat{R}_L(250), \hat{R}_U(250)) = \begin{cases} (0.741, 0.947), & \text{from the Normal approximation of } \hat{\lambda} \\ (0.719, 0.923), & \text{from the Normal approximation of } \hat{\lambda}^{1/3} \\ (0.716, 0.920), & \text{from the chi-square approximation of } 2r\lambda/\hat{\lambda}. \end{cases}$$

In addition, from Equation (23), the approximate 95% confidence interval for $R(250)$ based on the logit transformation results in (0.708, 0.917), since the estimated variance (35) is equal to 0.00274 and $w_{0.025}(0.838) = 2.130$.

Owing to the small size of the sample, the confidence interval (0.741, 0.947) based on the Normal approximation of $\hat{\lambda}$ should be discarded. The remaining three approximations should work all better, and give confidence intervals for $R(250)$ quite close each other.

Note that all the parametric confidence intervals for $R(250)$ are much narrower than the nonparametric intervals $(\hat{R}_L(250), \hat{R}_U(250))$ estimated in section titled ‘‘Complete and Singly Right Censored Samples.’’ This depends on the fact that the parametric approach uses not only the *sample* information (i.e., the information contained into the observed data), but also the *technical* information provided by the functional form chosen for the probability model. Of course, if the assumed model is not adequate, then both the estimate $\hat{R}(t)$ and the confidence interval $(\hat{R}_L(t), \hat{R}_U(t))$ are wrong, and the more the random variable deviates from exponentiality, the worse the parametric estimates are.

Data from the Two-Parameter Weibull Distribution

Let $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ indicate a random sample of size n of exact failure and right censored data from a two-parameter Weibull random variable with density function:

$$f(t; \theta, \beta) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1} \exp \left[- \left(\frac{t}{\theta} \right)^{\beta} \right], \\ \theta, \beta > 0, t \geq 0, \quad (37)$$

where $z_{0.025} = -1.960$, $\chi_{0.975}^2(17) = 30.191$, and $\chi_{0.025}^2(17) = 7.564$. Then, by using Equation (34), approximate 95% confidence intervals for $R(250)$ are

and reliability function:

$$R(t; \theta, \beta) = \exp \left[- \left(\frac{t}{\theta} \right)^{\beta} \right], \theta, \beta > 0. \quad (38)$$

The likelihood function $L(\theta, \beta; \mathbf{t})$ results in

$$L(\theta, \beta; \mathbf{t}) \propto \prod_{i=1}^n \left\{ \left(\frac{\beta}{\theta} \right)^{\delta_i} \left(\frac{t_i}{\theta} \right)^{\delta_i(\beta-1)} \right. \\ \left. \times \exp \left[-\delta_i \left(\frac{t_i}{\theta} \right)^{\beta} \right] \exp \left[-(1-\delta_i) \cdot \left(\frac{t_i}{\theta} \right)^{\beta} \right] \right\} \\ = \frac{\beta^r}{\theta^{r\beta}} \left(\prod_{i=1}^n t_i^{\delta_i} \right)^{\beta-1} \exp \left[- \left(\frac{\sum_{i=1}^n t_i^{\beta}}{\theta^{\beta}} \right) \right],$$

where $\sum_{i=1}^n \delta_i = r$ is the number of exact failure times. The log-likelihood function $\ell(\theta, \beta; \mathbf{t})$ is

$$\ell(\theta, \beta; \mathbf{t}) = r \ln \beta - r \beta \ln \theta + (\beta - 1) \\ \times \sum_{i=1}^n (\delta_i \ln t_i) - \left(\frac{\sum_{i=1}^n t_i^{\beta}}{\theta^{\beta}} \right), \quad (39)$$

and the ML estimate of the scale parameter θ is given by

$$\hat{\theta} = \left(\frac{\sum_{i=1}^n t_i^{\hat{\beta}}}{r} \right)^{1/\hat{\beta}}, \quad (40)$$

where the ML estimate $\hat{\beta}$ of the shape parameter β is the solution of

$$\frac{1}{\hat{\beta}} + \frac{\sum_{i=1}^n \delta_i \ln t_i}{r} - \frac{\sum_{i=1}^n t_i^{\hat{\beta}} \ln t_i}{\sum_{i=1}^n t_i^{\hat{\beta}}} = 0. \quad (41)$$

The ML estimate of the reliability $R(t; \theta, \beta)$ at any time $t \geq 0$ is

$$\hat{R}(t) = \exp \left[- \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}} \right]. \quad (42)$$

The ML estimate of the reliability at a given time x , say $R_x \equiv R(x)$, can also be obtained directly reparameterizing the log-likelihood function in terms of R_x and β . In this case, being $\theta = x/[\ln(1/R_x)]^{1/\beta}$, the reparameterized density and reliability functions result in

$$f(t; R_x, \beta) = \frac{\beta}{x} \left(\frac{t}{x} \right)^{\beta-1} \ln(R_x) R_x^{(t/x)^\beta}, \quad 0 \leq R_x \leq 1, \beta > 0, t \geq 0, \quad (43)$$

$$R(t; R_x, \beta) = R_x^{(t/x)^\beta}, \quad 0 \leq R_x \leq 1, \beta > 0, t \geq 0. \quad (44)$$

Expressions (43) and (44) are then used to obtain the reparameterized log-likelihood function $l(R_x, \beta; \mathbf{t})$. Maximizing $l(R_x, \beta; \mathbf{t})$ with respect to R_x and β gives the same ML estimates $\hat{R}_x = \hat{R}(x)$ and $\hat{\beta}$ as those obtained by maximizing the log-likelihood Equation (39).

In the case of complete samples, the distribution of $\hat{R}(t)$ depends only on $R(t)$ and n . The ML estimator (42) is the nearly minimum variance unbiased estimator of $R(t)$: the bias $E\{\hat{R}(t) - R(t)\}$, given in Table 5 of Ref. 20, is quite small, and it does not seem worthwhile to attempt to eliminate it. For Type II censored samples, the distribution of $\hat{R}(t)$ depends on $R(t)$, n , and r , and the bias of $\hat{R}(t)$ is still small, at least in the large range of investigation of Ref. 21.

For complete data, exploiting the above-mentioned properties of the distribution

of $\hat{R}(t)$, exact lower confidence limits for $R(t)$ were obtained by using a Monte Carlo simulation method and are tabulated in Ref. 22. Alternatively, such limits could be obtained through an iterative procedure illustrated in Ref. 20. However, such a procedure is somewhat inconvenient, and then $(1 - \alpha)$ lower confidence limits can be read directly from the extensive Table 7A of Ref. 20, given for n ranging from 8 up to 100, $\hat{R}(t) = 0.50(0.02)0.98$, $\alpha = 0.25, 0.15, 0.10, 0.05$, and 0.02 .

Simple approximate $(1 - \alpha)$ confidence intervals for $R(t)$ can be obtained from Equation (21) (for large samples) or Equation (23) (for small or moderate samples), where an estimate of $\text{Var}(\hat{R}(t))$ can be obtained through the delta method:

$$\begin{aligned} \hat{\text{Var}}(\hat{R}(t)) &= \left[\frac{\partial R(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \right]^2 \hat{\text{Var}}(\hat{\theta}) \\ &+ \left[\frac{\partial R(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \right]^2 \hat{\text{Var}}(\hat{\beta}) \\ &+ 2 \frac{\partial R(t)}{\partial \theta} \Big|_{\hat{\theta}, \hat{\beta}} \frac{\partial R(t)}{\partial \beta} \Big|_{\hat{\theta}, \hat{\beta}} \\ &\times \hat{\text{Cov}}(\hat{\theta}, \hat{\beta}), \end{aligned} \quad (45)$$

where $\hat{\text{Var}}(\hat{\theta})$, $\hat{\text{Var}}(\hat{\beta})$, and $\hat{\text{Cov}}(\hat{\theta}, \hat{\beta})$ are the elements (1, 1), (2, 2), and (1, 2), respectively, of the estimated asymptotic variance-covariance matrix $\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta})$, and the partial derivatives of $R(t)$ with respect to the model parameters, say

$$\begin{aligned} \frac{\partial R(t)}{\partial \theta} &= \left(\frac{\beta}{\theta} \right) \left(\frac{t}{\theta} \right)^{\beta} \exp \left[- \left(\frac{t}{\theta} \right)^{\beta} \right] \text{ and} \\ \frac{\partial R(t)}{\partial \beta} &= \left[\left(\frac{t}{\theta} \right)^{\beta} \beta \ln \left(\frac{t}{\theta} \right) \right] \exp \left[- \left(\frac{t}{\theta} \right)^{\beta} \right], \end{aligned}$$

are evaluated at the ML estimates $\hat{\theta}$ and $\hat{\beta}$. For complete samples, the asymptotic matrix $\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta})$ is [1,20]

$$\hat{\mathbf{V}}(\hat{\theta}, \hat{\beta}) = \begin{bmatrix} \left(\frac{\hat{\theta}}{\hat{\beta}} \right)^2 \frac{1.1087}{n} & \hat{\theta} \frac{0.2570}{n} \\ \hat{\theta} \frac{0.2570}{n} & \hat{\beta}^2 \frac{0.6079}{n} \end{bmatrix}. \quad (46)$$

As an alternative, the $(1 - \alpha)$ confidence interval proposed in Ref. 13 can be adopted:

$$(\hat{R}_L(t), \hat{R}_U(t)) = (\exp[-\exp(\hat{u}_U)], \exp[-\exp(\hat{u}_L)]), \quad (47)$$

where

$$(\hat{u}_L, \hat{u}_U) = \left(\hat{u} + z_{\alpha/2} \sqrt{\hat{Var}(\hat{u})}, \hat{u} - z_{\alpha/2} \sqrt{\hat{Var}(\hat{u})} \right),$$

$\hat{u} \equiv \ln[\hat{H}(t)] = \hat{\beta} \ln(t/\hat{\theta})$, and the asymptotic variance of $\hat{u}$ can be obtained through the delta method as follows:

$$\begin{aligned} \hat{Var}(\hat{u}) &= \left(\frac{\hat{\beta}}{\hat{\theta}} \right)^2 \hat{Var}(\hat{\theta}) + \left(\frac{\hat{u}}{\hat{\beta}} \right)^2 \\ &\quad \times \hat{Var}(\hat{\beta}) - 2 \frac{\hat{u}}{\hat{\theta}} \hat{Cov}(\hat{\theta}, \hat{\beta}). \end{aligned}$$

Using the asymptotic matrix (46), we have $\hat{Var}(\hat{u}) = (1.1087 + 0.6079\hat{u}^2 - 0.5140\hat{u})/n$. Confidence limits (47) are always within $(0, 1)$ for any $t > 0$ and any sample size. A very similar approximation is suggested by Ref. 1, which uses different coefficients to estimate the asymptotic variance of $\hat{u}$: $\hat{Var}(\hat{u}) = (1.1680 + 1.1000\hat{u}^2 - 0.1913\hat{u})/n$.

In the case of Type II censored sample, exact $(1 - \alpha)$ lower confidence limits can be read from Table 7B of Ref. 20, given for $n = 40(20)120$, $\hat{R}(t)$ ranging from 0.70 up to 0.999, $\alpha = 0.10, 0.05, 0.02$, and 0.01, and censoring level $r/n = 0.75$ and 0.50. Such limits can be used as approximate limits for Type I censored samples, too. As an alternative, the approximation (21) (suitable for large samples) or (23) (suitable for small or moderate samples) can be used, by estimating the asymptotic variance $\text{Var}(\hat{R}(t))$ through Equation (45) and computing the asymptotic matrix $\hat{V}(\hat{\theta}, \hat{\beta})$ as described in the section titled "Appendix." However, for singly censored samples, the matrix $\hat{V}(\hat{\theta}, \hat{\beta})$ can be easily read from tables in Ref. 23 too, as a function of the standardized censoring time $\zeta = [\ln T_C - \ln \hat{\theta}] \hat{\beta}$, where T_C is the censoring time. The matrix is the same for singly Type I and II censored data.

Table 4. Life Test Data of a Certain Type of Electromechanical Device in Example 4

i	t_i (h)	δ_i	i	t_i (h)	δ_i
1	1138	1	7	5046	1
2	1944	1	8	5139	1
3	2764	1	9	5500	0
4	2846	1	10	5500	0
5	3246	1	11	5500	0
6	3803	1	12	5500	0

Example 4. Let us consider the Type I censored data referring to $n = 12$ units of an electromechanical device given by Ref. [13]. All the tests were stopped at the time $T_C = 5500$ h and $r = 8$ failures were observed at times $t_1, t_2, \dots, t_8$ (see Table 4, where $\delta_i = 1$ if the time t_i is an exact failure time, and $\delta_i = 0$ if t_i is a right censored observation). By solving Equation (41), the ML estimate of β is $\hat{\beta} = 2.055$, from which, by using Equation (40), the ML estimate of θ is

$$\hat{\theta} = \left(\frac{\sum_{i=1}^{12} t_i^{2.055}}{8} \right)^{1/2.055} = 5215 \text{ h.}$$

The ML estimate of the reliability at the time $t = 4000$ h is computed from Equation (42): $\hat{R}(4000) = \exp[-(4000/5215)^{2.055}] = 0.560$. Unlike the nonparametric procedures, the ML procedure allows the reliability function $R(t)$ to be estimated also for times t greater than the largest observed time $t_{\max} = 5500$ h. For example, for $t = 8000$ h, still from Equation (42), we have $\hat{R}(8000) = \exp[-(8000/5215)^{2.055}] = 0.090$.

The approximate 90% confidence interval (23) for $\hat{R}(T)$ at $t = 4000$ h, based on the logit transformation, results in

$$(\hat{R}_L(4000), \hat{R}_U(4000)) = (0.320, 0.775),$$

being

$$\hat{V}(\hat{\theta}, \hat{\beta}) = \begin{pmatrix} 825042 \text{ h}^2 & -90.815 \text{ h} \\ -90.815 \text{ h} & 0.4117 \end{pmatrix},$$

$$\hat{Var}(\hat{R}(4000)) = 0.02230, \text{ and } w_{0.05}(\hat{R}) = 2.710.$$

GRAPHICAL PROCEDURE: PROBABILITY PLOTS

Estimate of the reliability function $R(t)$ can be easily performed via *probability charts*. This procedure can be used in the case the random variable T either pertains to the location-scale family or admits a transformation $\psi(T)$, which in turn leads to a location-scale distribution. More formally, it is required that the cumulative distribution function $F(t) = 1 - R(t)$ of the random variable T can be expressed as

$$F(t; a, b) = \Phi\left(\frac{\psi(t) - a}{b}\right), \quad (48)$$

being $\Phi(\bullet)$ a function independent of any unknown parameter. The parameters a and b are called *location* and *scale parameters*, respectively.

Then, the probability chart is obtained by adopting a $\psi(t)$ scale on the data axis (the x axis) and a $\Phi^{-1}(F)$ scale on the probability axis (the y axis). On this *model-dependent* chart, the plot of $F(t)$ versus t appears as a straight line. For example, in the case of the two-parameter Weibull model, the cumulative distribution function $F(t) = 1 - \exp[-(t/\theta)^\beta]$ can be linearized as it follows:

$$\ln \{\ln [1/(1 - F(t))]\} = \beta \ln t - \beta \ln \theta, \quad (49)$$

so that, for a two-parameter Weibull variable, $\psi(T) = \ln T$, $a = \ln \theta$, $b = 1/\beta$, and $\Phi^{-1}(F) = \ln \{\ln [1/(1 - F(t))]\}$, being $\Phi(\bullet) = 1 - \exp[-\exp(\bullet)]$ a function without unknown parameters.

Probability charts are available for many probability distributions widely used in reliability study, such as the standard exponential, the two-parameter Weibull, and the lognormal distributions.

In order to use probability charts, each ordered failure time $t_{(i)}$ ($i = 1, 2, \dots$) must be plotted on the chart against an estimate of $F(t)$ at that time, say F_i . These estimates of $F(t)$, named *plotting positions*, are obtained via a nonparametric approach. Only failure data are plotted on the probability chart, and not censoring times. Thus, plotting positions must be evaluated only at failure times.

Once the data are plotted on the chosen probability plot, it is necessary to fit a straight line through the points $(t_{(i)}, F_i)$, because the use of plotting positions inevitably produces departure from linearity. Very often the fitting is performed by sight, but a more accurate fit can be obtained by means of analytical methods, such as the least squares method [2]. The graphical estimate of $F(x)$ at a given time x of interest is then given by the ordinate (i.e., the value on the probability axis) of the point on the straight line having abscissa x .

Plotting Positions

In the case of complete or singly censored samples, the plotting position F_i for the i th ordered failure time $t_{(i)}$ ($i = 1, 2, \dots, r$) can be calculated as [2]:

$$F_i = \frac{i - 0.5}{n}, \quad i = 1, 2, \dots, r, \quad (50)$$

where n is the size of the sample and $r \leq n$ is the number of failure times in the sample. Other plotting positions, such as $F_i = i/(n + 1)$ and $F_i = (i - 0.3)/(n + 0.4)$, can be used. In the case of multiply censored samples without tied failure times, the plotting position F_i relative to the i th ordered failure time $t_{(i)}$ can be obtained via the Herd-Johnson estimator [1]:

$$F_i = 1 - \prod_{j=1}^i \left(\frac{k_j}{k_j + 1} \right), \quad i = 1, 2, \dots, r, \quad (51)$$

where k_i is the number of units at risk immediately before the ordered failure time $t_{(i)}$. In the case of tied failure times, the plotting position F_i has to be estimated at any distinct (ordered) time $x_{(i)}$ ($i = 1, 2, \dots, h$) at which one or more failures occur, by using

$$F_i = 1 - \prod_{j=1}^i \left(\frac{k_j - d_j + 1}{k_j + 1} \right), \quad i = 1, 2, \dots, h, \quad (52)$$

where d_j indicates the number of failures that occurred at $x_{(i)}$. Finally, for interval data, the plotting positions can be obtained from the actuarial estimators (15) or (16).

Figure 3. Graphical estimate of $F(4000)$ and $F(8000)$ in Example 4.

Table 5. Ordered Failure Times $t_{(i)}$ ($i = 1, 2, \dots, 8$) and the Corresponding Plotting Positions F_i in Example 4

i	$t_{(i)}$ (h)	F_i	i	$t_{(i)}$ (h)	F_i
1	1138	0.042	5	3246	0.375
2	1944	0.125	6	3803	0.458
3	2764	0.208	7	5046	0.542
4	2846	0.292	8	5139	0.625

Example 4 (continued). By using the life test data of the Type I censored sample of Table 4, we are interested in estimating, via a graphical procedure, the reliability of the electromechanical devices at the times $t = 4000$ h and $t = 8000$ h, under the assumption that failure times follow a two-parameter Weibull distribution. The plotting positions F_i are estimated via Equation (50) for each ordered failure time $t_{(i)}$ ($i = 1, 2, \dots, 8$), as given in Table 5. Once points $(t_{(i)}, F_i)$ are plotted on a Weibull chart and the straight line is fitted by sight, the

graphical estimate of the reliability is given by $\tilde{R}(4000) = 1 - \tilde{F}(4000) = 1 - 0.42 = 0.58$ and $\tilde{R}(8000) = 0.11$, as depicted in Fig. 3.

APPENDIX

The estimated $l \times l$ asymptotic variance-covariance matrix $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ of the parameter vector $\boldsymbol{\theta} = (\theta_1, \theta_2, \dots, \theta_l)$ is the inverse of the estimated information matrix $\hat{\mathbf{J}}(\hat{\boldsymbol{\theta}})$, whose entries are the negative second derivatives of the log-likelihood function $\ell(\boldsymbol{\theta}; t)$ with respect to the model parameters θ evaluated at the ML estimates $\hat{\boldsymbol{\theta}} : \hat{\mathbf{V}}(\hat{\boldsymbol{\theta}}) = [\hat{\mathbf{J}}(\hat{\boldsymbol{\theta}})]^{-1}$.

For a right censored sample $\mathbf{t} = \{t_1, t_2, \dots, t_n\}$ from a two-parameter Weibull distribution with scale parameters θ and shape parameter β (see section titled “Data from the Two-Parameter Weibull Distribution”), the estimated 2×2 information matrix results in

$$\hat{\mathbf{J}}(\hat{\theta}, \hat{\beta}) = \begin{pmatrix} r \left(\frac{\hat{\beta}}{\hat{\theta}} \right)^2 & -\frac{\hat{\beta}}{\hat{\theta}} \sum_{i=1}^n \left(\frac{t_i}{\hat{\theta}} \right)^{\hat{\beta}} \ln \left(\frac{t_i}{\hat{\theta}} \right) \\ -\frac{\hat{\beta}}{\hat{\theta}} \sum_{i=1}^n \left(\frac{t_i}{\hat{\theta}} \right)^{\hat{\beta}} \ln \left(\frac{t_i}{\hat{\theta}} \right) & \frac{r}{\hat{\beta}^2} + \sum_{i=1}^n \left(\frac{t_i}{\hat{\theta}} \right)^{\hat{\beta}} \left[\ln \left(\frac{t_i}{\hat{\theta}} \right) \right]^2 \end{pmatrix}, \quad (53)$$

where r ($r \leq n$) is the number of exact failure times.

ESTONIAN OPERATIONAL RESEARCH SOCIETY

OTU VAARMANN
Institute of Cybernetics at
TUT, Department of
Mechanics and Applied
Mathematics, Tallinn,
Estonia

The *Estonian Operational Research Society* (EstORS) — *Eesti Operatsioonianalüüsi Selts* in Estonian — was founded by Dr. Toomas Meressoo [Estonian Scientific Foundation (ESF), Management Board] and Prof. Otu Vaarmann [Institute of Cybernetics at Tallinn University of Technology (TUT), Department of Mechanics and Applied Mathematics] on 18th March, 2010. At the extended meeting (General Assembly) of the society, including 22 participants from different Estonian universities and research institutes, on 6th April, 2010, the Management Board (Directive Board), composed of seven members, was elected: Otu Vaarmann was elected as president (Chairman of the Management Board); Assoc. Prof. Peep Miidla [University of Tartu (UT), Institute of Applied Mathematics]; vice president and IFORS representative; Mrs. Marje Tamm [Institute of Cybernetics at TUT, Library], secretary; Dr. Harald Kitzmann [Tallinn University of Technology (TUT), Tallinn School of Economics and Business Administration], Treasurer; and Prof. Jaan Janno [Tallinn University of Technology (TUT), Department of Mathematics], Prof. Jaan Lellep [University of Tartu (UT), Department of Mathematics], and Dr. Toomas Meressoo (ESF), members. Dr. Tiit Riismaa [Institute of Cybernetics at TUT, Department of Mechanics and Applied Mathematics] was elected as the auditor of the society. In accordance with the decision of the Management Board on 6th April, 2010, the application form for membership asking to admit the Estonian Operational Society to IFORS was sent to the IFORS secretary

on 22nd June, 2010, and in March 2011, the Estonian Operational Research Society has been accepted as the fifty-second national member of IFORS. Estonia, with its 1.34 million inhabitants, is one of the smallest members of the European Union.

EstORS is a sovereign voluntary nonprofit organization located in Estonian Republic, Tallinn (<http://www.ioc.ee/matem/estors/>). EstORS will be ruled and regulated by its statutes in accordance with the Constitution of the Estonian Republic as well as pertinent Estonian Laws and Regulations. The society unites the experts in the field of Operational Research/Industrial Mathematics and its applications, actively working for development of Estonian Republic as an information society. According to its statutory mission, EstORS aims at contributing to the progress of scientific and technical knowledge, integrating competence Engineering Science and Management Science/Operations Research (OR), creating and transferring scientific knowledge in Informatics and Decision Systems.

Every person or juridical person who is actively working for achieving the goals and objectives of the society and fulfilling the requirements of the statutes may be a member of the society. The members may belong to the following categories: founding members, active members, honorary members, and contributor members.

The founding members are those who are admitted within a 30-day period following this act.

The active members are those who have been included in the social register after 30 days passed from the society foundation event and who have regularly complied with the obligations imposed by the statutes.

The honorary members are those who attend to their merits or to relevant services given to the institution are judged by the General Assembly.

The contributor members are those who have not fulfilled all the requisites established to the active members.

In all cases, the members may be Estonian citizen or foreigners. The decision on admittance or withdrawal will be taken by the Management Board (Directive Board). The former member may be accepted once more to the society after one year of withdrawal under the common conditions.

The General Assembly consists of all the members having the right to participate, and for those having the right to vote, their vote will be counted equally. The General Assembly will meet either ordinarily or extraordinarily to treat exclusively the themes and items within a previously announced agenda. The General Assembly accepts the statutes, formulates the changes and basic directions of the society, and is convoked by the Management Board at least once a year.

The society will be administered and represented by the Management Board composed of at least one member and supremely of seven members. The members and the chairman of the Management Board (the president), as well as the members of Auditing Commission (or the Auditor), will be appointed by the General Assembly to hold their post for three years. Sessions of the Management Board will be held no rarer than once in a half year.

Main purposes of the society are

- to encourage theoretical and applied researchers in the field of OR to contribute to the creation of new knowledge in Informatics and Decision Making (DM) from the viewpoint of science, technology, and innovation;
- to participate with the other institutions in the elaboration of developmental policies for disciplines related to the scope of this society;
- to promote the establishment of international contacts and stimulate further advancement of academic links and free exchange of experience between its members and members of other similar scientific societies belonging to this country, this region, and the world;
- to organize national and international meetings (conferences, seminars, exhibitions, etc.) related to the subjects, scope, and objectives of the society;
- to contribute to the distribution of scientific and academic contributions obtained by the society and its members by advocating the achievements in the field of OR by means of lectures, publishing books and papers;
- to encourage the teaching of OR and to this end to create funds and courses for raising the level of the skills in the field of OR/DM.

The society plans to introduce a new Master Curriculum on Industrial Mathematics in accordance with ECMI (European Consortium For Mathematics in Industry) corresponding to Model Curriculum. Through the cooperative effort of mathematicians, engineers, and experts in science, the society also aims to develop educational materials that link mathematical topics with applications in engineering, management, and science that will be suitable for further education and self-study for students. Further, the society concerns itself with mathematical education and broader relationship between mathematics and society. The society intends to advance a variety of educational cooperation activities between partners in the area of lifelong learning from the countries in the Baltic and Nordic regions. Currently, specialization in OR can be found in Estonia mainly at TUT and UT.

Public decision making typically involves complex optimization problems with several conflicting goals from very different backgrounds (environmental planning and management of environmental problems, natural resource management, reallocations of land uses, conservation biodiversity, analysis of logistic problems, disaster management, etc.), and there is a great demand for the assessment of the ongoing sustainable management by use of criteria and indicators in questions. Therefore, in decision-making tasks where trade-offs between economic development and environmental quality are indispensable, a Pareto-optimal solution provided by parallel use of cost-benefit

analysis (CBA) and multicriteria decision analysis (MCDA) is desirable. The measurement of the level of sustainability for a certain economic activity is a difficult task involving uncertainties and subjective considerations, and there is not yet a general consensus on how to measure sustainability. Multicriteria analysis provides powerful and widely used techniques for the appraisal of complex decision problems and the analysis of sustainability. Many multicriteria decision problems can be posed as a multiobjective

optimization problem to find adequate solutions to many challenging problems in business, technology, and society as a whole.

Although our subsequent research is to a high degree focused on multicriteria analysis and large-scale and/or multiple-objective optimization problems, the society also plans more widely to embark on projects to improve the attitude toward mathematics, which, it hopes, will result in more widespread use of OR.

EULERIAN PATH AND TOUR PROBLEMS

Tempe, Arizona

HISTORY OF THE EULERIAN TOUR PROBLEM

Routing problems play a very important role in service delivery. These problems arise in a large number of real-world applications such as postal delivery, electric and water meter reading, garbage collection, and snow clearance. Designing efficient routes for people and vehicles delivering these services has been a problem of interest for operations researchers and mathematicians. Such routing problems are of two types — node routing and arc routing problems — depending on whether the service request is at a node or on an arc/edge of the underlying graph. The underlying problem for most arc routing problems is determining a giant tour that starts and ends at a designated node and traverses all edges requiring service at least once. A tour (or circuit) is Eulerian if it starts at a designated node and traverses every edge in the graph exactly once before returning to the designated starting node. Given a graph and a starting node, the *Eulerian tour problem* (ETP) seeks to determine an Eulerian tour (or circuit), if one exists, or to show that the underlying graph does not contain an Eulerian tour.

The origins of the ETP can be traced back to the eighteenth century. The Pregel River flowed through the city of Königsberg in Eastern Prussia and enveloped the small island of Kneiphof before it split into two. The city had a total of seven bridges that were built across the river and connected the island and various parts of the mainland. Figure 1 shows

the orientation of the city and the bridges. Many people tried to determine if one could start at the end of a particular bridge and come back to the same point after traversing each of the seven bridges exactly once. It was believed that it was impossible, but no one could prove it. In 1735, Swiss mathematician, Leonard Euler showed that it is not possible to come back to the same point after traversing each bridge exactly once [1]. He showed that in order to come back to the same point after traversing each edge (or bridge) exactly once, every node in the underlying graph should be of even degree. In the Königsberg bridge problem, three of the nodes have a degree of three and one has a degree of five (Fig. 1).

Alexandersan [2] provides a detailed historical account of Leonard Euler's work on the Königsberg bridges and how and when his work was published. Facsimiles of Euler's original work have been published in Euler [3], and English translations of the original paper can be found in Fleischner [4]. Euler's work was essentially the beginning of many interesting graph theory studies, and hence, graphs that satisfy this condition have been termed *Eulerian graphs*. Eulerian graphs are also called *unicursal graphs* in graph theory.

In this paper, we present research related to the ETP. The ETP seeks to determine a tour that starts and ends at the same node and traverses all the edges in the graph exactly once or to show that the graph is not Eulerian. The next section introduces the basic notation and presents algorithms for determining an Eulerian tour in undirected, directed, and mixed Eulerian graphs. An undirected graph contains only undirected edges connecting the vertices of the graph, that is, the connecting links can be traversed in either direction. In a directed graph, every link connecting two vertices has a direction of traversal associated with it and the link (or arc) can be traversed only in that direction. A mixed graph contains a mix of both undirected and directed edges connecting the vertices. A connected undirected graph is

Figure 1. Seven bridges of Königsberg.

Eulerian if and only if every node has an even degree. A connected directed graph is Eulerian if and only if the in-degree of every vertex is equal to its out-degree. A mixed graph is Eulerian if all nodes have an even degree, and for each node, the number of arcs directed toward it is the same as the number of arcs directed away from it.

A graph is semi-Eulerian if and only if it is connected on all nodes except two that are of even degree. In a semi-Eulerian graph, we can determine an Eulerian path (or trail), that is, a path that traverses each arc or edge exactly once and starts and ends at the two nodes of odd degree. By adding an edge between the two nodes of odd degree, we get an Eulerian graph. We can then determine an Eulerian tour using the algorithms described below and then remove the edge that was added to obtain the Eulerian path (or trail). Hence, for the remainder of the paper, we have described the algorithms for Eulerian tours and concluded with areas of future research.

It is interesting to note that not all graphs are Eulerian, as in the case of the Königsberg bridge problem. In these cases, one might still be interested in determining an Eulerian tour on the underlying graph. This forms an interesting routing problem called the *Chinese postman problem* (CPP). The objective here is to determine the set of edges to be added to the graph at the lowest cost (distance) possible in order to make it Eulerian. Edmonds and Johnson [5] show that the CPP can be solved in polynomial time for undirected graphs using an adaptation of Edmond's blossom algorithm. This problem is called the *undirected CPP*. While the CPP

for directed graphs is also solvable in polynomial time, it is NP-hard when the underlying graph contains both arcs and edges. In this case, heuristics are used to make the graph Eulerian. For more detailed information on the least cost augmentation problem, see the articles *Matching and Assignment Algorithms* and *Chinese Postman Problem* in this encyclopedia.

ALGORITHMS FOR THE EULERIAN TOUR PROBLEM

In this paper, we assume that we are given an Eulerian graph $G = (V, E)$, and hence, the ETP seeks to determine an Eulerian tour (or circuit) on the underlying graph. Several algorithms have been proposed for determining Eulerian tours for directed, undirected, and mixed graphs. We next present a summary of these algorithms and direct the readers to appropriate references for detailed descriptions and proofs of the algorithms.

Undirected Eulerian Graphs

Euler [1] showed that an undirected graph is unicursal or Eulerian if and only if every node in the graph is of even degree. One of the earliest algorithms for the ETP on undirected graphs is described in Berge. Kaufmann later describes the same algorithm as Fleury's algorithm [6,7]. This is a very simple algorithm which depends on avoiding an *isthmus* or *bridge* in the graph. An *isthmus* or *bridge* is an edge in a connected graph whose removal disconnects the underlying graph.

Fleury's Algorithm.

- Step 1.* Mark all the edges in the graph as *unmarked*. Start at any node v_0 . Set $v_i = v_0$.
- Step 2.* From all the *unmarked* edges incident to v_i , pick an edge (v_i, v_j) that is not an *isthmus*. Remove edge (v_i, v_j) from the graph. If all edges have been removed, stop. If not, go to step 3.
- Step 3.* Set $v_i = v_j$ and go to step 2.

The algorithm is computationally expensive since at each step, one has to determine whether the chosen edge is an isthmus of the graph with unmarked edges. While the graph traversal in Fleury's algorithm is linear in the number of edges, that is, $O(|E|)$, we also need to factor in the complexity of detecting bridges, which is also linear in the number of edges, $O(|E|)$. Hence, Fleury's algorithm will have a time complexity of $O(|E|^2)$. Edmonds and Johnson [5] have proposed three alternate algorithms that are computationally simpler. These are the end-pairing algorithm, next-node algorithm, and the maze-search algorithm. All three algorithms essentially form one or more small tours that do not share any edges and then combine these tours to form a giant Eulerian tour. The three algorithms proposed by Edmonds and Johnson [5] are of $O(|E|)$ time complexity. We next present simple descriptions of the algorithms. See Edmonds and Johnson [5] for detailed algorithmic descriptions and proofs. The end-pairing algorithm represents the tour as $(v_0, e_1, v_1, e_2, \dots, v_0)$.

End-Pairing Algorithm.

- Step 1.* Start at node v_0 . Trace a simple tour starting and ending at node v_0 . If the tour includes all the edges in the graph, stop. If not, go to step 2.
- Step 2:* Consider any node v_i on the tour that has at least one edge incident to it and not on the tour. Trace another tour starting and ending at node v_i and using edges not on the first tour.
- Step 3:* If $v_i = v_0$, follow the first tour and then the second. If v_i is not equal to v_0 , then let e^1 and e^2 be two edges incident

to node v_i on the first tour and e^3 and e^4 be two edges incident to node v_i on the second tour. Interject the second tour on the first one as follows. Start at node v_0 . Follow the first tour to reach node v_i through edge e^1 , then follow the second tour through e^3 and return to node v_i through e^4 , and trace the remainder of the first tour through edge e^2 to return to v_0 . If the merged tour includes all edges in the graph, stop. If not, go to step 2.

Figure 2 shows a simple undirected Eulerian graph with five nodes and eight edges. Let us assume that the algorithm starts at node 1. The simple tour traced in step 1 is 1-2-5-1. If the next node chosen in step 2 is node 2 and the traced tour is 2-4-3-2, then $e^1 = (1, 2)$, $e^2 = (2, 5)$, $e^3 = (2, 4)$, and $e^4 = (3, 2)$. Step 3 would lead to the longer tour 1-2-4-3-2-5-1. The next simple traced tour will be 1-3-1. Since this tour originates at the origin of the appended tour, the final Eulerian tour will be 1-2-4-3-2-5-1-3-1.

In the next-node and maze-search algorithms, a tour is represented by associating a list of nodes for each node v_i . The list for each node v_i is obtained using the algorithm and is represented as $L_{v_i}(1), L_{v_i}(2), \dots, L_{v_i}(k)$. The list indicates the next node to go to when leaving node v_i .

Figure 2. Example graph to demonstrate the end-pairing and next-node algorithms.

Next-Node Algorithm.

Step 1: Pick any node v_0 . Set $v = v_0$ and $k_i = 0$ for all nodes i . Let e be any edge incident to node v . All edges are *unmarked*.

Step 2: Let v_i be the node adjacent to node v on edge e . Let $k_{v_i} = k_{v_i} + 1$ and $L_{v_i}(k_{v_i}) = v$. Edge e is *marked* as used. If v_i has any other *unmarked* edges incident to it, go to step 3. If not, node v_i should now be v_0 . Go to step 4.

Step 3: Set $v = v_i$ and let e be any *unmarked* edge incident to v_i . Go to step 2.

Step 4: Let v_0 be any node with at least one *marked* and one *unmarked* edge incident to it. Set $v = v_0$, and go to step 2. If no such node exists, stop.

At the end of the algorithm, each node has its own list of nodes. The first time node v_i is reached, we leave it through node $L_{v_i}(k)$, the second time through node $L_{v_i}(k - 1)$, and the last time through node $L_{v_i}(1)$. For the graph in Figure 2, the algorithm starts at node 1, and scans the edges in the following order (1,2), (2,3), (3,4), (4,2), (2,5), (5,1), (1,3), and (3,1). Hence, the nodes have the following lists. $L_1(1) = 5$, $L_1(2) = 3$; $L_2(1) = 1$, $L_2(2) = 4$; $L_3(1) = 2$, $L_3(2) = 1$; $L_4(1) = 3$; and $L_5(1) = 2$. Now the Eulerian tour is represented as 1-3-1-5-2-4-3-2-1.

Maze-Search Algorithm.

The algorithm is similar to the next-node algorithm. While the end-pairing and next-node algorithms provided a representation of the Eulerian tour without traversing it, the maze-search algorithm actually traverses the tour. When the next-node algorithm has completed a tour and there are still some *unmarked* edges left, the algorithm moves to any node on the tour that is incident to at least one *unmarked* edge and forms another tour and interjects that tour on the original tour. On the other hand, the maze-search algorithm retraces the path from the start node until it finds the first node with at least one

unmarked edge and forms another tour. When there are no *unmarked* edges left, the algorithm retraces the tour from the last node to the start node. Thus, in the maze-search algorithm every edge is traversed twice. The order of the second traversal gives the actual Eulerian tour. Edmonds and Johnson [5, page 114] provide a detailed description of the maze-search algorithm.

Directed Eulerian Graphs

In a directed graph, every edge in the graph is either directed toward or away from a node. A directed graph is symmetric if the in-degree of every node is equal to its out-degree. A directed graph is Eulerian if and only if it is connected and symmetric. van Aardenne-Ehrenfest and de Bruijn [8] have described the spanning arborescence algorithm to determine an Eulerian tour in a directed Eulerian graph.

An arborescence is a directed graph in which, for a vertex v_0 called the *root* and any other vertex v , there is exactly one directed path from v_0 to v . In other words, an arborescence is a directed, rooted tree in which all edges point away from the root. If every node other than the root node of the arborescence has in-degree (out-degree) at most 1, it is referred to as an out-tree arborescence (in-tree arborescence). A spanning arborescence is an arborescence whose underlying undirected graph is a spanning tree.

Spanning Arborescence Algorithm.

Step 1. Construct a spanning arborescence with a root node v_0 .

Step 2. Label all the edges of the graph consecutively as follows. Start at the root node v_0 , and number the edges out of this node arbitrarily. The remaining nodes can be visited for numbering the outgoing edges in an arbitrary manner. For each node, number the edges out of the node consecutively while taking note of the following two requirements. If there is an edge from the node back

Figure 3. Directed graph and associated spanning arborescence.

to the root node, it will be numbered last. The edge used by the spanning arborescence outgoing from the node will receive the penultimate number in the ordering.

Step 3. The Eulerian tour can be traced by starting at the root node and traversing any edge incident to it. At all other nodes, traverse the lowest numbered edge. Stop when there are no edges remaining in the graph.

Figure 3a shows a directed Eulerian graph with five nodes and nine directed edges and a spanning arborescence for the graph. The graph is connected and symmetric. Hence, it is clear that the graph is Eulerian. The spanning arborescence is rooted at node 1 and has a directed path to the other four nodes from node 1. Figure 3b shows the numbering of the directed edges according to step 2 of the algorithm. For the given spanning arborescence and ordering, the Eulerian tour is 1-2-3-5-4-2-5-3-4-1. Note that one can use this algorithm to find more than one Eulerian tour. If we use a different ordering for visiting the nodes and for numbering the edges out of each node in step 2, we will trace a different Eulerian tour. A different spanning arborescence rooted at the same node or at a different node would again lead to another set of Eulerian tours. The important step in the algorithm is to find a spanning arborescence, which can be accomplished in $O(|E|)$ time complexity. The other steps require scanning each edge once, and hence, the time complexity of the algorithm is $O(|E|)$.

Mixed Eulerian Graphs

A mixed graph is one in which some edges are undirected and some are directed. A mixed graph is said to be balanced if for any subset S of the nodes in the graph, the differences between the number of edges directed from S to V/S and the number of edges directed from V/S to S is no greater than the number of undirected edges between S and V/S . A mixed graph is even if all nodes have an even degree, and the graph is symmetric if for every node, the number of edges directed toward the node is the same as the number of edges directed away from the node. A mixed graph is Eulerian if and only if it is connected, even, and balanced [9]. If a graph is even and symmetric, it is balanced and hence, Eulerian.

In order to prove the balanced condition of the graph, Ford and Fulkerson [[9], p. 60] show that we need to establish a circulation in G , and then direct some of the undirected edges according to the circulation. They force a unit flow on every directed edge of the graph and replace each undirected edge with a pair of opposite directed edges with a lower bound of 0 and an upper bound of 1. The balanced condition basically shows that there is sufficient escape capacity from S to V/S to take care of the forced flow on the directed edges. If this is true for every set S , then a feasible circulation exists. In order to prove this, Ford and Fulkerson suggest adding a source node (s), a sink node (t), and the arcs (s, t) and (t, s) with infinite capacity to the graph. If we solve the maximal flow problem on this network, we obtain a feasible circulation in

G. The details of the procedure are described below.

Converting a Mixed Graph to a Symmetric Graph.

- Step 1.* For each directed edge in the original graph, assign a lower bound of 1 and an upper bound of 1. Now replace each undirected edge with a pair of opposite directed edges, each of which has a lower bound of 0 and an upper bound of 1.
- Step 2.* Solve the network flow problem on this appended graph to obtain a feasible circulation.
- Step 3.* If (v_i, v_j) is an undirected edge in the original graph and the flow from v_i to v_j is 1 and the flow from v_j to v_i is 0, then orient the undirected edge (v_i, v_j) from v_i to v_j .

The maximum flow in the graph can be calculated on $O(|E|f)$ time using the Ford–Fulkerson algorithm, where f is the maximum flow. A variation of the algorithm, developed by Edmonds and Karp [10], can determine the maximum flow in $O(|V||E|^2)$ time. If the resulting graph contains only directed edges, the van Aardenne-Ehrenfest and de Bruijn algorithm described in the previous section can be used to determine the Eulerian tour. If the graph still contains undirected edges, we can easily assign directions to the remaining undirected edges using the following $O(|E|)$ procedure, and then use the spanning arborescence algorithm. The procedure to assign directions to the undirected edges is as described in Eiselt *et al.* [[11], p. XX].

- Step 1.* If there are no undirected edges, stop.
- Step 2.* Pick a node v that is incident to at least one undirected edge (v, w) . Set $v_i = v$ and $v_j = w$.
- Step 3.* Orient (v_i, v_j) from v_i to v_j . If $v_j = v$, go to step 1.
- Step 4.* Set $v_i = v_j$, and find an edge incident to v_i . Go to step 3.

At the end of this procedure, the mixed graph is transformed to a directed Eulerian graph, and one can use the spanning arborescence algorithm to determine an Eulerian tour.

CONCLUSION

In this paper, we have presented a historical overview of the ETP and summarized the main algorithms for finding an Eulerian tour in undirected, directed, and mixed unicursal graphs. There exist quite a few situations in practice, when not all the edges of the Eulerian graph need to be visited everyday. That is, the probability that an edge has to be visited on any given day could be less than one. This can be modeled as a stochastic Eulerian tour problem (SETP). While the deterministic version of the ETP presented in this paper has a long history and is well researched, the stochastic ETP is very new. Further research should lead to the investigation of the stochastic CPP and development of good heuristics for the SETP as well as the other stochastic arc routing problems.

EVACUATION PLANNING

EVA REGNIER

Associate Professor of Decision
Science, Defense Resources
Management Institute Naval
Postgraduate School, Monterey,
California,

Since the September 11 terrorist attacks, there has been an explosion of Operations Research (OR) work applied to the preparation for and response to disasters, primarily human-caused disasters. Hurricane Katrina in 2005 prompted a second wave of OR efforts to prevent and mitigate the impacts of natural disasters.

Yet, the existing OR literature on evacuation planning is quite sparse; Wright *et al.* [1] surveyed the use of OR methods in homeland security and identified 14 articles on evacuation models. Despite the recent surge of interest in response to disasters, including hurricanes, OR work on evacuation planning has not increased noticeably.

This article outlines the types of decisions involved in evacuation planning, and briefly describes the OR modeling and solution techniques that can and have been applied. For readers interested in a review, the Wright *et al.* review is fairly complete to the date of this writing, with a few recent contributions cited later in this article. This article also highlights challenges to deploying OR tools in evacuation planning and OR's limitations, and problems that OR cannot address without substantial contribution from or collaboration with other fields of expertise.

EVACUATIONS AND EVACUATION PLANNING

Evacuation is the rapid movement of people, usually away from a localized hazard, and with little or no lead time. Evacuations can occur from a large geographic region—for

example, to avoid a hurricane—or from a single building, aircraft, or ship. Evacuation may involve pedestrians, vehicles, aircraft, watercraft, rail networks or combinations. They may be centrally directed or (more frequently) resulting from the collective behavior of many individual agents, be they individuals, families, or vehicles. Evacuation planning therefore, provides many important problems to which OR can contribute.

Evacuations vary tremendously in scope and type, and may be very complex, involving many decisions that affect their progress and effectiveness. The following describes some of the dimensions across which evacuation scenarios differ, and that largely determine the relevant type of decisions, modeling, and analyses:

- *No Notice versus Short Notice.* In many cases, the hazard that necessitates an evacuation occurs without warning and therefore, evacuation is initiated after the hazard's impact has begun. Examples include evacuating an aircraft following a crash or failure, evacuating a city or region during a fire or following an industrial accident (e.g., nuclear or chemical), or a terrorist attack. Even when there is no notice of the precipitating event, the impacts may continue to worsen following the initial event; for example, a fire may be spreading through a building. In other cases—for example, an earthquake—the extent of the hazard may be reached before evacuation begins, but evacuation is necessary to be able to provide care for those in the region.

In contrast, some types of hazard provide advance warning (short notice) and therefore, the evacuation may be initiated before the hazard impact occurs. Hazards that may provide warning include hurricanes and some terrorist threats.

- *Lead Time.* A related factor is how much time is available to complete the evacuation. Almost by definition, evacuations are completed with urgency, and in many cases, OR formulations minimize evacuation time (or maximize the number of people evacuated within a given time). However, there are degrees of urgency. For example, evacuations to avoid a hurricane have a lead time of up to several days. Trade-offs between speed of evacuation and completeness or cost come into play, and the amount of lead time dictates how important speed will be relative to other objectives and other factors that may be modeled. The amount of lead time available for evacuation before the hazard impacts occur is usually uncertain, but there may be some basis for a deterministic or probabilistic estimate, as with a hurricane.
- *Scale—Number of People.* A key dimension differentiating evacuations is their scale. Evacuations from aircraft, vessels, or buildings may involve a handful to a few thousand people. Large-scale evacuations may involve tens or, potentially, even hundreds of thousands of people.
- *Scale—Spatial.* The spatial scale of the evacuation is highly correlated with the number of people involved; evacuations that involve tens of thousands of evacuees are regional and will involve moving evacuees tens to hundreds of miles. As will be discussed below, the types of decisions and the types of modeling involved in planning for small- versus large-scale decisions will be quite different.
- *Predictability.* A further set of issues relates to the degree to which important parameters—such as evacuation zones, number of evacuees, and capacity within the infrastructure—can be anticipated before the precipitating event. In most cases, a building evacuation is relatively predictable once it is initiated. Generally, the entire building would be evacuated at once; the number of people in each area can be known within relatively narrow bounds. In contrast, with wildfires, these parameters are much more variable: the evacuation zones are not known, the number of people in each area may be highly variable by time of day or season, the response rate is uncertain, and so on. Furthermore, some threats may evolve over time, requiring evacuation of more or different areas (e.g., through the spread of fire) or cutting off escape routes (e.g., flooding roadways during a hurricane). The evolution may be uncertain. These differences may require very different modeling techniques; for example, uncertainty must be modeled for highly unpredictable evacuations. The types of decisions that are most important will also be different as a function of predictability; for example, the importance of information-gathering and communication will be much greater for highly unpredictable evacuations.

Two important characteristics of evacuations have been omitted from the taxonomy: mode of transportation and type of physical infrastructure. The mode of transportation is tightly linked with scale, for instance

Table 1. Application of the Taxonomy to Three Evacuations: the World Trade Center (WTC) Evacuation on September 11, the 2008 Evacuation in Advance of Hurricane Ike, and the December 2008 Aircraft Evacuation at the Denver Airport

Dimension	WTC 2001	Hurricane Ike	Denver Jet
Lead time	None to minutes	Days to a week	None
Scale—people	Thousands	One million	115
Scale—spatial	Hundreds of vertical/horizontal feet	Tens to hundreds of miles	Hundreds of feet
Predictability	Medium	Low	High

evacuations of aircraft, vessels, and buildings are typically pedestrian evacuations. Smaller-scale evacuations, for example from within a few city blocks, may also be pedestrian-based. Larger-scale evacuations in developed regions will usually involve vehicles. The infrastructure usually provides structure and constraints on the evacuation and the modeling effort. Although transportation mode and infrastructure determine what an evacuation looks like, the same types of decisions and models may be used for pedestrians and for vehicles, for road networks, and within buildings.

Table 1 categorizes three recent evacuations according to these dimensions to illustrate some of the critical differences among evacuations. The evacuation of the WTC on September 11, 2001 was initiated after the precipitating event, that is, after the tower was struck by an attacking aircraft. Between the time of the first impact and the collapse of the second tower, less than 102 min passed [2]. Although evacuation recommendations were, in some cases, delayed or poorly communicated, 13,000–15,000 people exited, traveling down from their offices and leaving the immediate area. The evacuation of the WTC on September 11 was a pedestrian evacuation of a building or set of buildings. Some people in the second tower hit (the first to collapse) had minutes of warning that there was a hazard, so arguably the lead time was up to several minutes. The predictability is categorized as “medium” because although the specific nature of the hazard, the areas that were destroyed or became impassable were not anticipated, the need to evacuate the entire complex had been anticipated; there had even been drills and education of the employees working in the building prior to September 11 incident.

Similarly, the evacuation of the jet that ran off the runway in Denver in December 2008 [3] was not specifically anticipated; however, the need to evacuate the entire aircraft had been considered during the design of the aircraft. The passengers and crew escaped using inflatable slides that were provided specifically to be used in the event of an evacuation.

In contrast, the evacuation of many areas in the Houston and Galveston Texas area in advance of Hurricane Ike in 2008 was initiated for special needs residents over three days in advance of landfall. This was part of a much larger evacuation of the region, in which about a million people left their homes, and many moved tens to hundreds of miles. The evacuation was conducted primarily in personal vehicles, and via a transportation network. Unlike the other two evacuations, it was initiated several days before the hazardous conditions occurred. The storm itself had been tracked for several days prior to the actual evacuation, and preparations and decision making for the evacuation had begun. For major hurricane evacuations, the need for an evacuation may be considered up to a week before the actual impacts.

The remainder of this section briefly describes variables that planners can control that may influence the outcome of an evacuation, and are therefore the decisions whose effects may be analyzed in OR modeling efforts.

Ultimately, a complex network of interacting agents and organizations—ranging from individuals to community organizations to government agencies—collectively determines the course and effectiveness of an evacuation [4,5]. To their frustration, OR analysts cannot dictate individuals’ evacuation behavior, even if armed with an optimal and robust evacuation plan. However, both advance planning and interventions undertaken immediately preceding and during the course of an evacuation can determine constraints on and influence individuals’ evacuation behavior.

Decisions that may be taken after a hazard or threat of hazard necessitating an evacuation becomes known may be informed by details about the specific threat and in some cases, specific information about the population at risk and resources available at the time. The relevant decisions may be called *operational planning*. For large-scale evacuations, some of these actions may even be dynamically updated in real time in response to information about the progress of the evacuation. These actions include the following:

- *Communication.* In many cases, the most important short-term action that officials can take is to communicate with the affected population. Many types of decisions may be involved, such as the type of evacuation, which is mandatory, recommended, or voluntary [6]. In addition, the problem of targeting populations to receive evacuation warnings may be complex. “Shadow” evacuations of those who are not at risk in their homes may interfere with the evacuation of those who need to move, as the overevacuation during Hurricane Rita in 2005 illustrated. Moreover, messages may need to be coordinated across jurisdictional boundaries.
- *Short-Term Modifications to the Network.* Although the basic structure of the physical infrastructure will be determined far in advance of a specific threat, some adjustments in the structure of a transportation network may be made in response to a particular evacuation. This is most applicable in a large-scale evacuation occurring on a road network. With enough lead time, it is possible to change the flow patterns, by opening or closing routes, or by reversing traffic flow on key routes out of the area (contraflow). Within the road network, public transportation such as buses may also be provided. In addition, transportation network capacity may be increased; for example, rail resources may be pre-positioned by rescheduling passenger trains to transport people out of the evacuation zone.
- *Providing Resources to Facilitate/Support Evacuation.* Resources that either speed evacuation or encourage more people to evacuate by making the evacuation more comfortable, may also be deployed within evacuation time-scale. To make evacuation via a road network more efficient, officials may deploy personnel to direct traffic and provide roadside services, including fuel and equipment for removing disabled vehicles. In addition, providing supplies and other resources for evacuees en route or at designated destinations

may encourage evacuation, speed evacuation, or improve the outcomes for the evacuees, thus enhancing the likelihood that they will evacuate in the case of future emergencies. Resources that may be provided en route include food, water, fuel, and other necessities, medical supplies or care; these may be essential during an evacuation in which evacuees spend many hours on the road, as in the 1999 Hurricane Floyd and 2005 Hurricane Rita evacuations. Similarly, providing staffing and provisioning evacuation destinations such as shelters may encourage people to evacuate and then to proceed to these shelters. In the case of a large-scale evacuation, many evacuees travel hundreds of miles to stay with family or friends. This adds to the burden on the road network, and may slow the evacuation. In some cases, providing nearby shelters that people will consider acceptable options may reduce the total number of evacuee-miles traveled, and facilitate the evacuation overall.

Many of the decisions that affect the outcome of an evacuation are made years in advance of any specific hazard that necessitates an evacuation. The most obvious examples are the design of infrastructure, which largely determines evacuation routes and their capacity, and thus long-range planning decisions, described below, often determine the constraints on the short-term actions described above and on individual evacuation behavior.

The main long-range planning decisions that relate to the design of the transportation network or infrastructure. Evacuations are also commonly considered in building design, and may affect the number of exits; number, size, and location of stairwells; even nonphysical parameters such as dedication of “express” elevators; and occupation limits. Evacuation is not usually an important consideration in the planning and design of road networks [6], although this may be changing; OR tools and expertise can contribute, as discussed later.

It should be noted that actions that may be implemented with little or no lead time still require advance planning—the plan itself must be available before the hazard—for example, it is usually impossible to both develop and implement an evacuation plan within the evacuation time-scale. The US Marine Corps faced this problem when Hurricane Floyd threatened Camp Lejeune in coastal North Carolina, and there was no evacuation plan in place. Ultimately, Camp Lejeune did not evacuate its personnel [7]. Wildfires can create a similar situation because they are so unpredictable in timing, extent, and evolution. In general, evacuation plans will not be in place when a wildfire begins.

It may be important to identify and communicate evacuation zones, destinations, and routes in advance, so that the messages at the time of the actual evacuation may be more effective. Within a building or craft, signs or other installed indications of evacuation routes are also long-lead actions that affect evacuation outcomes.

Underlying decisions about how to implement an evacuation are the decisions about whether and when to take action. These decisions should be made on the basis of information about the hazards, possible courses of action, and their consequences. They may (and should) therefore be informed by the results of analyses of the implementation decisions described above. The whether-and-when decisions are rarely addressed in the OR literature, but may be addressed with some OR tools.

OR TOOLS FOR EVACUATION PLANNING

This section describes readily applicable modeling techniques and/or results that have been or may be used to address the decisions outlined above. There has been surprisingly little application of modeling and formal analysis to evacuation planning for transportation networks. Wolshon *et al.* [6] offer several explanations including the fact that mass evacuations are infrequent, relative to other events around which transportation systems are designed. Another explanation is

the expectation that evacuations will necessarily overload transportation networks, and analysis would merely reveal this failure, and therefore cannot add much value.

Most modeling is used either as decision support or in long-range planning. In decision support for operational decision making, model results inform decision makers' subjective decisions. Most of the OR contributions are in the long-range planning stage. Wright *et al.*'s [1] review of OR contributions in homeland security identifies 14 articles from the broader literature (including non-OR journals) that address the evacuation stage of the disaster life cycle. Only one of these is categorized as relating to the "response" phase of the hazard life cycle. The remainder address decisions taking place earlier, during planning prior to evacuation.

The vast majority of existing applications in OR use one of two modeling approaches: network flows, or agent-based simulation. This section outlines the most common application of these approaches to evacuation planning, and describes more briefly some other approaches.

Network Flows

Network flow models are the most common OR tool used in evacuation planning (see the section titled "Network Flows" in this encyclopedia). Network flows have been applied primarily to small-scale evacuation problems, such as building evacuation, although network flows have been used for large-scale road networks as well.

The infrastructure in which the evacuation occurs is modeled as a network, and the flows consist of evacuees, who may be pedestrian or vehicular. In general, nodes represent sources of evacuees and destinations. Nodes also represent transshipment points, which are usually physical flow-through points, such as stairways or highway intersections, interchanges, and merge points. Depending on the model, arcs (usually directed) may represent physical flow-through points, or may represent the possibility of travel between two nodes, and may be capacitated.

In a static network flow evacuation model, arc costs usually represent transit time or

distance, and the solution minimizes some evacuation-time-related objective, such as time-to-destination of last evacuee, or mean evacuation time. In some cases, for example, Yamada [8] and Han *et al.* [9] the problem reduces to an assignment problem.

More common in evacuation planning is the dynamic network flow model, reapplied at multiple time-steps, as the flow moves through the network. Generally, nodes and/or arcs are capacitated—by flow per unit time—and arcs are cost-less. Chalmet *et al.* [10] provide the first example in the OR literature, and make use of Jarvis and Ratliff's [11] result showing that in a dynamic network flow, minimizing the time to complete flow through the network simultaneously minimizes the mean (or other monotonic time-weighted sum of) evacuation time and maximizes the flow completed at every time-step. Chiu *et al.* [12] provide the most recent example, and bridge the gaps between the civil engineering and OR languages and approaches to evacuation modeling.

A dynamic model allows for changes over time in the underlying network, such as implementation of short-term network changes (e.g., contraflow), the closure of parts of the network due to disaster impacts (e.g., flooding cutting off hurricane evacuation routes) or changes in capacity due to overcrowding or other effects.

Either static or dynamic network flow models may be used to optimize flows within a network as given, or to test the effect of changes in the network. Within a given network, an optimal network flow solution may yield an evacuation plan, which may be used to assign evacuees to routes or destinations. The solution may be implemented by designating evacuation routes or destinations in advance of the need for an evacuation, either by communicating to the public in advance or during an evacuation either in a permanent (e.g., building exit sign) or temporary (e.g., mobile highway sign) fashion.

The optimal network flow may also be used to estimate evacuation completion times, and indicate the lead time required to complete an evacuation before disaster occurs or interferes with evacuation.

Network flow models may also be used iteratively in design of the network, for example, in identifying bottlenecks, sizing points of egress, or deciding whether to implement contraflow. A network flow analysis may also be used during design or redesign of infrastructure, the network solution may identify bottlenecks and therefore indicate areas that should be expanded or otherwise improved. The network analysis may be run varying the conditions of the evacuation. For example, the sources may vary with the nature or location of the hazard. In this way, the network model may be used as a tool in infrastructure design.

Usually, the optimization would be completed in advance, but in the case of a proactive evacuation, a network optimization could be completed using hazard-specific information about sources and capacities (accounting, for example, for construction or other short-term changes in the network) and its results implemented in real time. The results would be difficult to implement in a building, but in the case of evacuation via a road or rail network, it may be possible to either require or recommend evacuation routes or destinations with short-term planning.

Network flow modeling is the most common approach to evacuation planning appearing in the OR literature; this is consistent with the review of disaster operations management research in OR/MS generally [13], which found that mathematical programming was by far the most common modeling approach in the broad literature surveyed, with probability and statistics a distant second, and simulation third.

Agent-Based Models

In contrast, civil and transportation engineering researchers use simulation as their primary quantitative modeling approach for evacuation planning. The most common approach—especially in recent years—is agent-based simulation in which multiple decision making agents, with independent rules of behavior, interact within a modeled infrastructure. With increasing computing power and commercialization of simulation software, agent-based simulation is

applicable to planning for both large- and small-scale evacuations.

Agent-based modeling contrasts with network flow modeling in that it can (at additional computational cost) incorporate more and more detailed elements of the transportation and evacuation systems. For example, agent-based simulations can include diverse individual behavior patterns that have a substantial impact on evacuation time estimates [14] and highly detailed descriptions of the infrastructure [see Ref. 15, e.g., a model of the effect of traffic signal timing]. Some of these models combine mathematical programming to model individual decisions with agent-based simulation, to describe the cumulative impact on the larger system [16]. Effects such as capacity reductions caused by congestion emerge from agent-based simulations.

Another reason for simulation's dominance among civil and transportation engineering studies is that the purpose in evacuation modeling is often to evaluate designs of modifications to the physical infrastructure, rather than control and/or policy selection. This is changing with the growing importance of intelligent transportation systems, allowing for real-time control using optimized policies or direct real-time human intervention [17].

Agent-based models are already heavily in use in emergency planning. These models are already commercialized and operational; see Refs 18 and 19, which describe models in use as decision support systems (DSS) for emergency managers, in long-range transportation planning and in academic research. They use the term "micro" models to describe agent-based models, because until recently, the computational requirements of agent-based models restricted their use to modeling small-scale evacuations, or only a small portion of a larger evacuation.

Most, if not all, of the models they describe as "macro" or "meso" models use empirical relationships to describe the capacity of elements of the road network, as a function of the traffic geometric design (the physical structure of the road network) and control conditions (e.g., traffic lights).

A few of the DSS use the output of agent-based simulations as input (e.g., Hurrevac, www.hurrevac.com).

Logistics Models

As discussed above, OR tools that are used to plan for supply chain of relief supplies or services may be relevant to evacuation planning, because they may encourage evacuation and make it more efficient and effective. Logistics for evacuation is challenging because the network must be set up with a short lead time, and is intended to be temporary.

These challenges are just the sort that the OR community has begun to tackle under the rubric of disaster logistics or humanitarian logistics. Both *Interfaces* (volume 36, issue 6, November–December 2006) and *IIE Transactions* (volume 39, issue 1, January 2007) have offered special issues on applications to homeland security. The problems treated include several that could apply to logistics support for evacuations, such as setting up supply chains with short notice (e.g., for medical response to bioterrorism incidents). Moreover, there are many recent initiatives in humanitarian logistics that address supply chain, inventory [20], routing [21], and facility location problems [22]; see also the section titled "Introduction to facility location" in this encyclopedia that could be applicable to providing for evacuees.

Stochastic Modeling and Optimization

In the case of proactive evacuations, there may be flexibility in the timing of the initiation of an evacuation [23]. Hurricane evacuations are an obvious example, and evacuations following a disaster such as an earthquake may also allow officials flexibility in deciding when to initiate the evacuation. OR modeling may help in deciding when to evacuate, a decision that may be made in conjunction with or with cognizance of other evacuation planning decisions. OR approaches such as stochastic modeling and optimization may be employed to support this decision, as Regnier and Harr [24] illustrate in a stylized example.

Decision Support Systems

As discussed earlier, Wright *et al.* [1] cited only one OR article addressing the “response” phase of an evacuation. The response phase encompasses all operational planning, that is decisions that may be made in the evacuation time-scale, immediately before, during, and immediately after the precipitating event [5]. Reference 12 is an important recent contribution to the response phase: it offers a dynamic network flow model that can be implemented in real time to generate optimal decisions about destination and route assignment. They also offer a good overview of prior evacuation research and models underlying existing operational decision support.

The remainder of the OR contributions identified by Wright *et al.* [1], however, are in DSS; that is, anticipated disaster scenarios are determined with advance analysis, and called up in real time to provide human decision makers with assessments of the consequences of decisions so that they can consider the effects, within the DSS model, of various alternatives before subjectively choosing the best, based on their judgment, training, and experience with prior evacuations, and with the model. Many of the DSS integrate other types and sources of information, such as weather forecasts (in Hurrevac, www.hurrevac.com) and geographic information systems (GIS). De Silva and Eglese [25] and de Silva *et al.* [26] describe some of the issues and approaches in GIS-based decision support.

Although the existing DSS have been developed in the civil engineering community (and are reviewed by Hardy and Wunderlich [19]), it is an area that is developing rapidly (Wolshon, personal communication) with increasing use of agent-based simulation and better user interfaces, and integration among models and data sources. The OR community has much to offer in this area.

Multiple-Objective Models

Evacuation planning involves many competing objectives. Many of these can be thought of as simply balancing costs against effectiveness; for example, investing in

infrastructure or providing services and supplies to evacuees are costly but may speed evacuation. Most evacuations have complex socioeconomic consequences and therefore, naturally lend themselves to the benefits of structured processes for identifying important underlying objectives, especially in group contexts, and for balancing these in optimization [27]; see also the sections titled “Normative Structuring of Decision Problems” and “Decision Aids for Improving Group Decisions” in this encyclopedia. The many, often competing, objectives involved in evacuation planning may include speed, completeness, voluntariness, compliance rates for current and future evacuations, as well as security and equity (e.g., priority or support for subpopulations).

CHALLENGES AND LIMITATIONS

This section briefly highlights some of the challenges for researchers and practitioners and limitations to the application of OR in evacuation planning as posed by complications in real-world evacuations that make extending OR models to evacuation modeling nontrivial.

Perhaps the biggest challenge is human beings: ultimately, a collection of individuals implements an evacuation. Identifying an optimal policy is useless unless it can be communicated effectively to the individuals who implement the evacuation. Ensuring that there are conduits for messages to the individuals involved in implementation may itself be a key decision problem. Increasing the effectiveness of the communication, that is, the likelihood that the individuals will respond as intended, may also be challenging.

It is highly unlikely that all or even most of those involved in an evacuation will follow a globally optimized policy, even if it is well-communicated and logistically supported. Agent-based simulation can address some of these issues, by using research on human behavior as the basis for agent models. Like any model, these will be imperfect and subject to the limitations of the available data about human behavior, which is especially limited for behavior in unusual circumstances such as disasters.

In addition to the inability to dictate individuals' behavior, there are other complications of modeling the flow of human beings. For example, an optimal network flow might have flow from a single node (whether source or transshipment node) on multiple arcs. This would be difficult to implement or communicate when the flow is human, though it might emerge naturally by individual choice.

For large-scale evacuations, implementing OR solutions can be difficult because of multiple loci of authority. In the United States, even for a relatively small area to be evacuated, there may be multiple layers of government, each with one or more agency involved. If the evacuation zone crosses jurisdictional boundaries, additional authorities with different roles, rules, and systems come into play, and coordination becomes even more difficult. Both within and across jurisdictional boundaries, officials in different roles may also be separated by the professional language and culture of their area of specialization. Moreover, nonpublic officials, such as churches and other community organizations may be involved. The Washington D.C. metropolitan area, which includes two states, the district itself, and 17 city or county governments attempted to develop a single evacuation plan for the event of a terrorist strike. Ultimately, officials abandoned the attempt, and settled for documenting the individual entities' plans [28]. The most important future contributions, with the greatest practical impact, will likely require inputs and interaction from emergency management, civil and transportation engineers and researchers from other disciplines including social sciences.

There are also technical challenges to modeling and/or designing transportation networks, such as the following:

- Emergency responders and logistics may use the same routes (simultaneously or near-simultaneously) that evacuees are using. Moreover, the infrastructure and the solution must both allow multiple types of flow.
- In a related problem, different types of models may be appropriate for logistics supply chain and transportation

networks. The most effective global solution to evacuation planning might require integrating multiple models and optimizing for many complex, inter-related decisions [30]. Simulation may be used to integrate multiple model types, but this of course increases computational requirements and complicates the definition of a solution and the appropriate analysis.

- Disruptions to the network are more likely in the case of an evacuation than in other transportation planning problems, and network disruptions may be uncertain. For example, a bridge might go down, or an evacuation shelter might be flooded or destroyed. To the extent that these disruptions are predictable—either deterministically or stochastically—they may be handled with dynamic networks or agent-based simulation, but these considerations expand the scope of the analysis.
- For analyses completed before a specific evacuation, the evacuation scenario will be unknown; for example, sources, supply at each source, available routes, available destinations may not be known, but paths may need to be determined *a priori*. Therefore, for certain types of planning, robustness of decisions to potential evacuation scenarios is important [29].
- Another potentially critical problem is the number of people who, because of their health or lack of access to resources, do not have the means to self-evacuate.

Evacuation planning includes many sub-problems that fit into the framework of OR tools, including network modeling, stochastic optimization, and large-scale agent-based simulation. At the same time, evacuation planning poses many challenges to a straightforward application of these or any purely quantitative tools. Many of the assumptions required for the application of even complex OR models—such as the assumption of central planning and a single objective function—break down in this context.

There are many challenges for finding OR solutions that can be implemented in practice. Evacuation planning problems

- may be subject to substantial uncertainties about key parameters;
- involve many decision makers, often including multiple authorities and many legitimate stakeholders;
- are dependent on human behavior that may be difficult to predict and for which few data are available to support modeling;
- involve many interacting subsystems, which may require different modeling approaches;
- require extensive and ongoing collaboration with other disciplines and with multiple stakeholders.

However, these challenges play to the strengths of some within the broad community of OR researchers and practitioners. In particular, evacuation planning can benefit from the OR community's experience and expertise in structuring problems with multiple interacting subsystems, identifying robust solutions to complex problems, and playing a consulting role in public-sector and multistakeholder contexts.

EVALUATING AND COMPARING FORECASTING MODELS

Engineering, Rutgers University,
Piscataway, New Jersey

INTRODUCTION

Strategic planning for the future is extremely important in any business to make definitive action plans. Owing to its great importance, the knowledge of forecasting has been growing very rapidly in modern times. Many forecasting models have been developed to empower people in decision-making for various application areas. For example, accurate demand forecasts are essential for manufacturers to determine the optimal production rate by making a trade-off between stock-outs and high inventory levels. Successful climate forecasting models have been developed to provide early warnings of adverse climatic conditions, such as hurricanes, storms, or fogs [1]. In business activities, forecasting technologies have become indispensable tools in a wide range of managerial decision-making processes, such as finance, banking, investments, employment, mortgages, and loans [2].

Forecasts can be made based on either empirical qualitative analysis or mathematical quantitative analysis. Accordingly, forecasting models can be broadly classified as qualitative methods and quantitative methods. The flowchart of a typical forecasting modeling process is shown in Fig. 1. And the categorization of forecasting models is shown in Fig. 2. Fildes and Lusk [3] argued that no forecasting method could be the “best” method among the various competing forecasting methods. All forecasting methods have distinct advantages and disadvantages. Therefore, selecting the right forecasting

method is of critical importance to all decision makers. This article briefly reviews the most influential forecasting models, and discusses the evaluating and comparing criteria/algorithms for model selection.

QUALITATIVE METHODS

Qualitative forecasting techniques rely primarily on human judgment based on expertise, experience, or intuition. They can be used in a wide range of circumstances where historical data are not available, or circumstances that are changing so rapidly that a mathematical forecasting model based on past data may become irrelevant or questionable. A number of qualitative forecasting methods have been developed to make good use of qualitative judgments from experts. Five of the more popular qualitative methods are briefly presented in the following.

Delphi Method

The Delphi method is a group technique, which is based on structural surveys of a panel of experts about their perceptions of future events [4]. All of the experts answer a series of survey questions anonymously in several rounds. In the first round, the panel members are asked to write down their intuitive forecasts on the survey papers. Then, all the responses are summarized and fed back to each of the panel members. In the next round, the panel members may modify their original forecasts based on the responses of other panel members. This process usually generates a narrowing of opinions, and can be stopped by a predefined criterion, such as maximum number of rounds, degree of consensus, or stability of results. The final result of the process can be the mean or median results of the final round. The Delphi method provides more accurate forecasts than face-to-face group discussions, which are often highly influenced by those experts who have the best interaction and persuasion

Figure 1. Flowchart of a typical forecasting modeling process.

Figure 2. Categorization of forecasting models.

skills, or powerful background. With the advances in collaborative tools, such as e-mail, synchronous video conference, and web conference, the Delphi Method is very easy to implement in modern times. However, one drawback of the Delphi method is that it is usually very time consuming.

Jury of Expert Opinion

The jury of expert opinion is a method of developing forecasts in which the executives of a company are polled for their best estimate of the future trends, such as likely sales and demands [5]. It is also known as the *jury of*

executive opinion method. This method is one of the simplest and widely used forecasting methods in business. A typical outline of the “jury of expert opinion” method is as follows. First, each executive gets familiar with the background information as much as possible. Then in the meeting, all the executives write their estimates on survey papers. The final step is to combine all the options to produce an average and acceptable result among all the executives. The “jury of expert opinion” method can be considered as an informal variant of the Delphi method. The only difference between them is that the “jury of expert

opinion” method does not have a mechanism to prevent interactions amongst the meeting participants.

Scenario Analysis

Scenario analysis is a systematic thinking process to discover how various factors may function together to create the future [6]. Different scenarios can be generated by combining different policy plans with all known facts and anticipated changes about the future. Scenario analysis can often lead to plausible forecasts if the causal relationship between factors and their consequences have been appropriately simulated. Decision-makers can learn from the outcomes of different scenarios without risking failures and losses in real business. To approach scenario analysis, the major steps are briefly as follows:

1. Determine the overall assumptions and factors on which the scenarios will be built. All assumptions and factors should be carefully made so that they can be conveniently under the user’s control and inspection. A time scope of the scenarios are also given.
2. Combine all the selected factors and assumptions together to construct a baseline framework. Each setting of the factors corresponds to a scenario. Given different levels of the influential factors, the outcome evolution of each scenario can be quite different.
3. Compare outcomes of the scenarios and pick up the most sensibly fitted scenarios. This step usually requires a considerable amount of debate to determine the selected scenarios.

Sales Force Composite

Other than management and administration members, sales force can also be an important factor for qualitative forecasting analysis. The most popular method is known as *sales force composite*, which is based on forecasts of salespeople [7]. The assumption of the “sales force composite” method is that salespeople are most qualified to predict future

market development in their own territories. Since salespeople interact directly with customers, they are presumed to have good estimates of market changes and trends. One possible disadvantage of this method is that forecasting results of salespeople tend to be optimistic. This is mainly because salespeople may always choose an optimistic prediction if a low estimate could endanger their employment status. Moreover, since the sales force in one department may not be aware of impending changes in other areas, the opinions of salespeople in different territories should be combined into consideration in decision making.

Market Survey

To forecast future trends, another popular qualitative approach is to ask customers or potential users how they foresee their future consumption of a product or service. It is also called the *user’s expectation* method. Since there is no benefit conflict, individual users are supposed to provide forecasts without undue optimism. Market survey has gained its popularity and importance in forecasting the success of new products [8]. However, one problem is that user opinions may be heavily biased by the trend of the moment. For example, most people have pessimistic opinions during periods of recession and have optimistic opinions in periods of growth and prosperity. Another disadvantage of the “market survey” method is that it is often very expensive to obtain a comprehensive survey of customer expectations.

QUANTITATIVE METHODS

Quantitative methods make forecasts based on mathematical models rather than subjective judgment. These methods are the mainstream of forecasting techniques as a result of the great advances in mathematical modeling and computational power in modern times. Quantitative forecasting models have been utilized across a wide spectrum of business and industry. As shown in Fig. 2, quantitative methods can be classified as noncausal models and causal models [9]. Noncausal models are also known as *time-series models*, which

make forecasts by extracting systematic patterns (such as trends and seasonality) from historical time series data. Causal models are also known as *cause-and-effect models*, which investigate how the variable being forecasted is determined by its relevant influential factors. We will take a brief look at the leading quantitative methods in the following.

Time Series Models

Time series models predict values of the variable being forecasted based on historical patterns. Thus the basic underlying assumption of these methods is that future patterns are similar to historical patterns. To extract characteristics of time series patterns, four basic properties of data are often analyzed.

- *Trend*. Given a set of time series data, the term *trend* refers to a stable tendency of growth or decline exhibited in the data. The trend of a time series can be either linear or nonlinear. Accordingly, linear and nonlinear functions can be utilized to model the trend.
- *Seasonality*. If a pattern always repeats at a fixed interval, it is called a *seasonal pattern*. Seasonality is a very common characteristic of time series data. For example, air temperature exhibits a strong yearly seasonal pattern.
- *Cycles*. Cyclic patterns are similar to seasonal patterns, except that they repeat at varying intervals. For example, it is common to find nonstationary cycles in financial time series data.
- *Randomness*. Most time series data are assumed to contain both systematic patterns and random noises. The randomness usually makes the pattern difficult to identify. Most time series models include a noise term to take into account the effects of randomness.

Various time series methods have been developed to analyze these properties of time series data. Five of the most popular ones are moving average (MA), exponential smoothing, Box–Jenkins models, state–space models, and spectral methods.

Moving Average (MA). MA models are simple but popular forecasting methods in time series analysis. An MA model involves taking the arithmetic average of N most recent observations, where N is a specific number according to the nature of the data to be forecasted. For example, if you are forecasting monthly sales, you might use 12-month MA model, which takes the average sales over the past 12 months. A one-step-ahead MA model of N periods is given by

$$\begin{aligned} F_{t+1} &= \frac{1}{N} \sum_{i=t-N+1}^t x_i \\ &= \frac{x_t + x_{t-1} + \cdots + x_{t-N+1}}{N}, \end{aligned} \quad (1)$$

where F_{t+1} is the forecast for the $t+1$ th period, and x_i s, $i = t-N+1, \dots, t$ are the observations in the past N periods. The mean of N most recent observations is used as the forecast of the next period. The MAs method is probably the most commonly used technique to smooth out short-term fluctuations and capture characteristics of varying trends in time series data.

Exponential Smoothing. Exponential smoothing assigns exponentially decreasing weights as observations getting older. The most commonly used single exponential smoothing is given by

$$F_0 = x_0, \quad (2)$$

$$F_{t+1} = \alpha x_t + (1 - \alpha)F_t = F_t + \alpha(x_t - F_t), \quad (3)$$

where $\alpha \in [0, 1]$ is the smoothing factor, F_{t+1} is the new forecast for next period, x_t is the current observation at period t , and F_t is the last forecast made in period $t-1$. In the above formula, one can substitute $F_t = \alpha x_{t-1} + (1 - \alpha)F_{t-1}$, and continue so forth to obtain the infinite expansion of F_t as follows

$$F_t = \sum_{i=0}^{\infty} \alpha(1 - \alpha)^i x_{t-i-1} = \sum_{i=0}^{\infty} \alpha_i x_{t-i-1}, \quad (4)$$

where $\alpha_i = \alpha(1 - \alpha)^i$. From this expression, one can see clearly that the weight α_i

decreases exponentially with time. This illustrates why this method is called *exponential smoothing*. Single exponential smoothing works best only for stationary time series data without trends and seasonality. There are two variants of exponential smoothing, known as double and triple exponential smoothing, respectively. In particular, double exponential smoothing can be applied to handle time series data with linear trends, and triple exponential smoothing is capable of dealing with both linear trends and seasonality. A very detailed discussion of exponential smoothing techniques can be found in Gardner [10,11].

Box–Jenkins Methods. Box–Jenkins methods, named after the statisticians George Box and Gwilym Jenkins, who applied autoregressive moving average (ARMA) to make forecasts for time series data [12]. An ARMA model can be generally described by

$$\begin{aligned} x_t &= c + \epsilon_t + a_1x_{t-1} + a_2x_{t-2} + \cdots + a_px_{t-p}, \\ &\quad - b_1\epsilon_{t-1} - b_2\epsilon_{t-2} - \cdots - b_q\epsilon_{t-q}, \quad (5) \\ &= c\epsilon_t + \sum_{i=1}^p a_i x_i - \sum_{j=1}^q b_j \epsilon_j, \end{aligned}$$

where x_t is the current observation, $x_{t-1}, \dots, x_{t-p}$ are the observations in the past p periods, and the $a_1, \dots, a_p$ are the regression coefficients of the past p observations. The ϵ_t is the current prediction error, the $\epsilon_{t-1}, \epsilon_{t-2}, \dots, \epsilon_{t-q}$ are the past q prediction errors, and the $b_0, b_1, \dots, b_q$ are the associated regression coefficients. ARMA models assume that the time series to be analyzed is stationary. To handle the non-stationarities such as trend and seasonality, Box and Jenkins proposed a differenced version of ARMA model, which is known as the *autoregressive integrated moving average* (ARIMA) model. The “I” stands for “integrated,” since the estimation process is performed on differenced data, and the time series needs to be integrated before making a forecast. For more mathematical details of the Box–Jenkins model, refer Box *et al.* [12].

State–Space Models. State–space models virtually build up a generalized representation of linear time series models in state space form. For example, one can represent an ARIMA model in state space form. Once a state space model is built, it can be conveniently analyzed by Kalman filter and the associated smoother. Kalman filter is a recursive procedure to compute the optimal estimator of the state vector at time t , based on the information available at time t . The parameters of a state space model are usually estimated by maximum likelihood functions. The state space method is a sophisticated form of forecasting models. A detailed discussion of various algorithms of state space models can be found in Harvey [13].

Spectral Analysis. Spectral analysis represents a group of methods, which decompose time series data into a few underlying sine and cosine functions of different frequencies. Compared to ARIMA or exponential smoothing techniques, for which the seasonal period is known as *a priori* in the analysis, spectrum analysis is suitable to deal with the seasonal series data for which lengths of cyclic patterns or fluctuations are changing rapidly or are difficult to estimate. In spectral analysis, some important recurring cycles of different frequencies in the time series can be discovered. Those patterns may be hidden in random noises and are extremely difficult to find out by other methods. The most common spectrum decomposition process is also referred as *Fourier analysis*, which can be considered as a linear multiple regression process. The dependent variable is the time series to be studied, and the independent variables are sine and cosine functions of all possible frequencies. In general, a spectral decomposition model is given by

$$\begin{aligned} x_t &= c + \sum_{j=1}^k (a_j \cos(\omega_j t) + b_j \sin(\omega_j t)), \\ 0 &< \omega_1 < \cdots < \omega_k < \pi, \quad (6) \end{aligned}$$

where $\omega_1 < \cdots < \omega_k$ are k possible wavelengths of the cyclic patterns in the time series, $a_1, a_2, \dots, a_k$, and $b_1, b_2, \dots, b_k$ are regression coefficients that represent the

degree of corresponding sinusoidal functions are correlated with the data. In other words, a large sine or cosine coefficient indicates a strong periodicity of the respective frequency in the data. There are various techniques available to perform spectral analysis for time series data. A comprehensive discussion of spectral analysis can be found in Koopmans [14].

Causal Models

Causal models are also known as *cause-and-effect models*, which establish a causal relationship between the variable being forecasted and all other related variables. The most well-known causal models are called *regression models*, which build up a rigorous mathematical model of causal relationship based on sound statistical techniques. In a regression model, the variable to be forecasted is called *dependent* or *response variable*, and the variables that represent the causal factors of the dependent variable are called *independent* or *explanatory variables*.

Regression Models. Regression models are in principle to investigate the relationship between one dependent variable and its relevant independent predictor variables. In general, a standard regression model takes the form as follows

$$Y = b_0 + b_1X_1 + b_2X_2 + \cdots + b_nX_n, \quad (7)$$

where Y is the forecasted value of the dependent variable, b_0 is the intercept, and $b_1, b_2, \dots, b_n$ are the estimated regression coefficients representing the contribution of the independent predictor variables $X_1, X_2, \dots, X_n$, respectively. When linear regression models do not appear to adequately capture the relationships between dependent and predictor variables, nonlinear regression models (such as polynomial regression) can be used. An overview of the popular nonlinear regression models can be found in Seber and Wild [15].

Econometrics Models. In many real problems, the cause-and-effect relationship between dependent and independent variables are not straightforward. The estimated

model parameters by the standard regression analysis may become inappropriate due to the highly dynamic relationship between the dependent and independent variables. For example, we wish to forecast sales of a product, which is related to its price. However, the market price in turn is also affected by sales. Another typical example is the supply and demand model. The interaction of supply and demand jointly determines the equilibrium price and quantity of the product in the market. In such cases, it no longer makes sense to separate dependent and independent variables completely. To handle this problem, a set of simultaneous regression models is necessary to describe dynamics of these systems. The simultaneous regression models are called *econometrics models* in literature, since they are often applied to analyze the relationships between economic variables that should be jointly determined. One can consider that a single regression model is a special case of econometrics models. The rigorous mathematical formulations of econometrics can be found in Pindyck and Rubinfeld [16].

ANN Models. Artificial neural networks (ANNs) represent another important form of causal models, which have shown powerful capabilities of modeling complex relationships between inputs and outputs. An ANN model consists of a network of neurons connected by arcs with assigned weights. Neurons take some form of basic nonlinear functions. Therefore, an ANN model can be equivalently considered as a nonlinear regression model in mathematics. A typical ANN has three layers, an input layer, a hidden layer, and an output layer. As a causal model, the inputs to an ANN are independent or explanatory variables, and the outputs are dependent or response variables being forecasted. There are various algorithms available to train ANNs, such as Perceptron learning rule and backpropagation [17]. Once the structure and weights of an ANN are determined, it can be employed to perform forecasting. ANNs have been increasingly used in forecast modeling in the past decade. They are suitable for complicated problems, which are difficult to

be mathematically formulated by regression models or econometric models. In many real applications, ANN methods can often achieve good performance if given enough training data. An overview of the applications of ANNs in forecasting can be found in Zhang *et al.* [18].

COMPARING AND SELECTING FORECASTING MODELS

We have discussed the most popular forecasting models above. Table 1 below summarizes the appropriateness of the three major types of forecasting models. To evaluate forecast models, two terms that are often of concern are accuracy and bias. *Accuracy* refers to the distance between the forecasts and actual values. And a forecast is biased if the errors in one direction are significantly larger than those in other directions. In general, the basic objective of all forecast models is to maximize accuracy and minimize bias. After fitting several model candidates to a given data set, the next step is to compare and select the best forecasting model. A lot of criteria have been proposed to compare forecasting models, which will be discussed in the following.

Forecast Error Measures

To achieve high prediction accuracy is the primary objective in most forecasting tasks. To evaluate forecasting accuracy, four of the more popular direct error measures are mean squared error (MSE), and its variants root mean squared error (RMSE), mean absolute error (MAE), and mean absolute percentage

error (MAPE). Minimizing these measures is usually the most essential criterion in comparing forecasting models. These measures are most frequently used due to their mathematical convenience. For each of these measures, a smaller value indicates higher prediction accuracy. Given a set of real data $y_i, i = 1, 2, \dots, n$, each of which has an associated forecast value $\hat{y}_i$, then these measures are defined as follows

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2, \quad (8)$$

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{n}}, \quad (9)$$

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^n |y_i - \hat{y}_i|, \quad (10)$$

$$\text{MAPE} = \frac{1}{n} \sum_{i=1}^n \left| \frac{y_i - \hat{y}_i}{y_i} \right|. \quad (11)$$

The R-squared (R^2), also known as *coefficient of determination*, is another most commonly used criterion to evaluate a forecast model. The most general form of the R^2 is defined as follows

$$R^2 = 1 - \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2} = 1 - \frac{SS_{\text{err}}}{SS_{\text{tot}}}, \quad (12)$$

where $\bar{y} = \sum_{i=1}^n y_i / n$, it is the mean of the observed data. The second term compares the variance of the forecast errors with the

Table 1. The Applicable Situations for Different Types of Forecasting Models

Model Type	Applicable Situations	Horizon	Data Types
Qualitative models	No past data, no ideas about causality, data too costly to collect, short-run accuracy not required.	Either long-run or short-run	Background information, survey
Time series models	Historical time series data available, stable patterns exist, short-run accuracy needed	Short-run	Time series data
Causal models	Past data available, causal relationship is clear and stable, explanatory variables are controllable	Short-run	Response and explanatory data

total variance of the data. One minus the second term is the proportion of variability in a data set that can be explained by the forecast model. R^2 is used to measure how well a model approximates real data values. The magnitude of R^2 is usually restricted within 0 and 1. An R^2 close to 1.0 indicates that the model perfectly fits the data, while an R^2 close to 0 means that the model cannot explain the data at all.

Information Criterion

A number of model selection criteria have also been developed based on information theory. A well-known criterion is Akaike's information criterion (AIC) developed by Akaike in 1974 [19]. It makes a trade-off between accuracy and complexity in model construction. In general, this criterion can be defined as

$$\text{AIC}(K) = \log(\text{MSE}) + \frac{2K}{n}, \quad (13)$$

where K is the number of variables in the model, n is the number of observations in the data. The MSE here is the same as defined in (9) and it can be explained as the estimated residual variance in this criterion. In the formula of AIC, the first term indicates model accuracy, and the second term indicates model complexity in terms of the number of variables. Hence AIC not only rewards prediction accuracy, but also imposes more penalty to larger number of model variables. One major benefit of this penalty is to discourage overfitting. For a set of models, the one with the lowest AIC value is considered as the preferred model. This criterion is particular suitable for comparing a set of nested models. For example, compare an $\text{AR}(m)$ model with an $\text{AR}(m+1)$ for a given set of data. One drawback of AIC is that it might not be consistent, since as the number of observations grows, the probability of selecting the correct model does not approach one.

The Bayesian information criterion (BIC), also known as the *Schwarz criterion*, is another well-known criterion to select a set of parametric models with different choices of explanatory variables [20]. BIC is actually

a variant of AIC in a form of

$$\text{BIC}(K) = \log(\text{MSE}) + \frac{\log(n)K}{n}. \quad (14)$$

The BIC also makes a trade-off between accuracy and complexity of a model. For a set of models, the one with the lowest value of BIC is the one to be preferred. It differs from AIC in that the penalty coefficient of K becomes $\log(n)/n$ instead of $2/n$. The BIC generally penalizes free variables more strongly than does the AIC. In addition, Hannan and Quinn [21] also proposed an alternative to AIC and BIC called *Hannan–Quinn criterion* (HQC), which is given by

$$\text{HQC}(K) = \log(\text{MSE}) + \frac{2K \ln \ln(n)}{n}. \quad (15)$$

Similar to AIC and BIC, the model with the lower value of HQC is preferred. It has been shown that consistency can be obtained by the BIC [20] or HQC [21,22].

Cross-Validation

Cross-validation is also a commonly used technique to compare different predictive models in practice [23]. Given a set of data, the basic idea of cross-validation is to partition the data set into training and validating subsets, and estimate the predictive accuracy on the validating data by the model obtained from the training data set. The MSE, RMSE, MAE, and MAPE can be used to measure the expected level of fit of a predictive model. If a model fits the training data set very well but does not fit the validation data, it is called *overfitting*. A good predictive model is supposed to generate consistent results in both training and validating data sets. To reduce the variability of the model evaluation, multiple trials of cross-validation are usually performed with respect to different partitions to the original data set. The evaluation result of a predictive model is the averaged result over these trials. There are several different approaches to perform multiple steps of cross-validation.

- *Repeated Random Partition Validation.* This method simply divides the dataset into two subsets randomly each time

and repeats the same procedure a number of times. One problem of this method is that the validation subsets may overlap and some observations may never be selected in the validation subsets.

- *K-Fold Cross-Validation.* The dataset is partitioned randomly into K subsets. Then the cross-validation is repeated K times. Each time one of the subsets is reserved as the validation data, and the remaining $K - 1$ subsets are the training data sets. The validation result is the average over K results. This approach guarantees that each observation can be used for validation exactly once.
- *Leave-One-Out Cross-Validation.* This method is actually a special case of K -fold cross-validation, when the number of observations in each subset is one. In other words, only one observation is reserved for validation and the remaining observations are used for training. The procedure is repeated until each observation has been used once for validation.

Stepwise Model Selection

Stepwise model selection approaches are very useful for automatically selecting a set of nested predictive models, for which there are a large number of potential predictive variables [24]. The selection procedure is generally grounded in some statistical tests and usually takes the form of the partial F -test. Other measures can also be used, such as t -tests, R^2 , AIC, and BIC. Since the basic procedures are similar, only the case of the partial F -test is discussed here. To compare two nested models with different number of predictor variables, the partial F -test can be generally formulated as follows

$$F = \frac{\text{Extra sum of squares/Extra model df}}{\text{SSR of the larger model / Residual df of the larger model}}, \quad (16)$$

where SSR denotes the sum of squared residual. The key idea of this test is to check

if the “extra” predictors of the larger model explain significantly more of the variability compared to the variability that is explained by the predictors that are already in the smaller model. On the basis of the partial F -test, three approaches are commonly used for model selection:

- *Forward Selection.* This starts with the smallest number of possible predictors and adds predictors one by one until a stop criterion is satisfied or the largest model is reached. The current model satisfying the stop criterion is selected. In particular, suppose that the current model has P variables, and we want to test if one of the model with $P + 1$ variables is more preferred. If for all models of $P + 1$ variables, it satisfies

$$F = \frac{\text{SSR}(P + 1) - \text{SSR}(P)}{\text{SSR}(P + 1)/n - P - 2} < F_c, \quad (17)$$

where F_c is the critical value of the F -statistic for a chosen level of significance, n is the total number of observations to fit the models, and $n - P - 2$ is the residual df of a model with $P + 1$ variables. Then stop the process and the current model with P variables is preferred. Otherwise, select one preferred model of $P + 1$ variables, and repeat the test for all models with $P + 2$ variables, and so forth.

- *Backward Selection.* This starts with the largest number of possible predictors and removes predictors one by one. Suppose the current model has P variables. Then at each step, it compares all the possible models of $P - 1$ variables with the current model. The process is stopped and the current model is selected, if the F -test statistic of each smaller models is not significant. That is, for all smaller models, it has

$$F = \frac{\text{SSR}(P - 1) - \text{SSR}(P)}{\text{SSR}(P)/n - P - 1} < F_c. \quad (18)$$

- *Stepwise Selection.* This is a modified version of forward selection, which allows the elimination of predictors that become statistically insignificant in the model. At each step of the process, the p values of all predictors are computed. If the largest of these p values is greater than a critical value, then the corresponding predictor is eliminated. Other steps are all the same as with those of forward selection.

Residual Diagnostics

Residuals represent the portion of the validation data not explained by the model. The graphical residual analysis is commonly used complementarily with quantitative techniques. A typical residual diagnostics includes plots of residuals versus the predicted values, versus other predictors, and versus time; residual autocorrelation plots; residual histograms; and normal probability plots. In general, the residual analysis can be used to test the following:

- Whiteness test: a good predictive model should have uncorrelated residuals.
- Independence test: a good model should have residuals uncorrelated with past inputs.
- If there are some extreme influential observations. Identifying and deleting outliers from the training dataset may significantly improve the quality of a model.
- If the residuals exhibit systematic patterns and bias. The residuals of a good model should be approximately dispersed around zero evenly. If systematic patterns are found, the most probable reason is that one or several relevant predictors are missing. A forecast is biased if residuals in one direction are significantly larger than those of the other direction.

Qualitative Considerations

Any forecasting model will be inevitably used by people. Thus qualitative considerations can also be a very important factor in evaluating various forecasting models. The qualitative criteria include intuitive reasonableness of the model, simplicity of the model, ease of use in practice, ease of explanation and understanding, and quality of forecast plots and demonstrations. Moreover, if two models have similar predictive performance, the simpler model is usually preferred. One famous principle is called *Occam's razor*, which suggests that when competing theoretical models are equal in other respects, it is recommended to select the model that introduces the fewest assumptions while still sufficiently answering the question. For more details of Occam's razor, refer to Soklakov [25].

CONCLUSION

This article reviews the most commonly used forecasting methods including both qualitative and quantitative methods. Quantitative methods are based on rigorous mathematical formulations, while qualitative methods are based on subjective judgment. Different forecasting methods have distinct different characteristics and applicable areas. To select appropriate forecasting models, one generally needs to consider the following important factors before model construction:

- What is the objective of forecasting, short-run or long-run?
- What types of data or explanatory variables are available?
- How much accuracy is required?
- Whether to make a trade-off between the costs and gains of developing a forecasting model.

Once a number of model candidates are selected, one should use one or more evaluation criteria to select the best forecasting model. Although quantitative models are mainstream approaches in forecasting, they are often used in combination with

qualitative techniques involving human judgment. Broadly speaking, quantitative methods usually provide tools for decision support, while quantitative and qualitative techniques together are used for decision making in most of the real-world cases. Therefore, a comprehensive assessment of forecasting performance usually consists of both quantitative and qualitative analyses to enhance the forecasting rationality in practice. A very good review of combining qualitative methods with quantitative techniques can be found in Webby and O'Connor [26] and Armstrong and Collopy [27].

EVALUATIONS OF SINGLE- AND REPEATED-PLAY GAMBLER

DOUGLAS H. WEDELL
Department of Psychology,
University of South Carolina,
Columbia, South Carolina

We encounter single instantiations of risky prospects on a regular basis, such as when we consider which car to purchase, which investment to make, or which health treatment option to choose. In each case, there is a single, unique outcome that we will experience. Regardless of whether the probability that the car we purchase will be a lemon is 1 in 10 or 5 in 10, we will experience only one of these outcomes. So even if we pick the safe outcome (1 in 10) we may still get burned. At other times, we may be considering a set of repeated instantiations tied to our choice. For example, instead of purchasing a single car, one may purchase a fleet of 100 cars for a company. In such cases, it is likely that a distribution of outcomes will be observed so that 1 in 10 would translate into roughly 10 of the 100 cars in the fleet being a lemon. If we consider health decisions, the same type of distinction can be made. We may contrast the idea of choosing between risky procedures for a single person (often ourselves), or developing a choice policy applied to a population of individuals, as a health-care administrator might do.

What difference does it make to evaluate a single instantiation versus multiple instantiations of a risky prospect? Should it make a difference? This article reviews changes in decision-making behavior, which occur when evaluating single versus repeated-play gambles, beginning with a discussion of normative issues. That discussion is followed by a review of relevant behavioral studies and then a summary of theoretical explanations for these evaluations and choice patterns.

NORMATIVE ISSUES

When von Neuman and Morgenstern [1] provided a normative basis for selecting the alternative with the highest expected utility (EU), they essentially argued that a long-run perspective be applied to each unique choice set one encounters. Because the concept of expectation is based on an analysis of aggregated outcomes, EU theory naturally incorporates a long-run strategy. But, people do not always find it easy to adopt a long-run perspective when considering unique instantiations of a choice set. Instead, choices made in the short run for unique single event options and in the long run for repeated or multiple instantiations of risky prospects often differ considerably.

The Nobel prize-winning economist, Paul Samuelson, examined the distinction between short- and long-run perspectives in a brief article he wrote revolving around the choice behavior of one of his colleagues. He described how his colleague refused to risk \$100 for a 50/50 chance to win \$200 [2]. Although this gamble has quite a high expected value ($EV = 0.50[-\$100] + 0.50[\$200] = \$50$), such a refusal is not problematic for EU theory, because a concave utility function could be constructed in which its EU would be less than the status quo. However, this choice became problematic when the colleague insisted he would be willing to place the bet if he were guaranteed a hundred such opportunities. Samuelson described the colleague's unwillingness to play the bet once but insistence on playing it 100 times as reflecting two different decision rules, one focused on the short run and the other on the long run, and he considered this inconsistency as irrational and a violation of EU theory.

Is it a violation of normative principles to choose differently for single and repeated risky prospects? Samuelson [2] sketched out a proof that was later fleshed out more

fully by Tversky and Bar-Hillel [3] describing when such behavior was inconsistent with EU theory. Samuelson acknowledges that refusing the single play but endorsing multiple plays can be accommodated by EU theory under some specific utility functions. However, he states that if one would refuse the single bet under all wealth levels described by the possible range of outcomes (in this case, $100[-\$100] = -\$10,000$ to $100[\$200] = \$20,000$), then it is inconsistent to accept the repeated version. Tversky and Bar-Hillel presented a more general proof that does not depend on using EU theory as the normative standard but only depends on accepting the normative principles of transitivity and dominance. Both these proofs consider the choice of the aggregate as the same as a series of single-play choices within the range of wealth levels. However, Aloysius [4] pointed out that equating the multiple-play choice with a series of single-play choices is not a valid assumption, and he demonstrated how EU theory can be consistent with the choice pattern of Samuelson's colleague under the conditions outlined in the proofs when consideration of the aggregate is based on current one's wealth state rather than wealth states at each sequential choice point. Lopes [5,6] has also argued for the rationality of this behavior on the basis of considerations outside of the realm of EU theory. Thus, there is still a good deal of controversy concerning the normative status of switching choices between single plays of a risky prospect and multiple or repeated plays of that prospect.

BEHAVIORAL FINDINGS

Before describing behavioral results, it is useful to clarify the distributional representations of the single- and multiple-play situations, the latter being a binomial distribution of outcomes. Figure 1 presents the distributions that correspond to (i) a single play of Samuelson's bet, (ii) 10 plays of this bet, and (iii) 10 plays of the bet with payoffs reduced by a factor of 10, equating EVs for single play and repeated plays. There are several distinctions that are immediately apparent when comparing a single play to

Figure 1. Outcome distributions for (a) one play of Samuelson's bet (50% chance to lose \$100 and 50% chance to win \$200), (b) 10 plays of the gamble, and (c) 10 plays of the gamble with outcomes reduced by a factor of 10.

multiple plays. As pointed out by Lopes [5,6], the EV of \$50 for Samuelson's bet does not correspond to any realized outcome in the single-play situation—one walks away either \$100 poorer or \$200 richer. In contrast, the EV is the modal value of the distribution for the 10-play situation (in this case, there is a probability of 0.2461 of walking away with the EV). Thus, with a single-play, EV is an abstract conception that does not match up with actual outcomes, whereas with repeated plays it is a tangible and typical result.

A second distinct feature of these distributions is that the probability of losing is quite different. With single plays, the probability of losing is simply $p = 0.50$, so that half of the time one will walk away a loser. With 10 plays, one needs to lose more than twice as often as win in order to end

up an overall loser, so that the probability of losing is only $p = 0.17$. If the bet were played 100 times, the probability of losing would reduce to less than 1 in 2000, radically different from the single-play situation. Of course, Samuelson [2] pointed out that the magnitude of the risk (i.e., variance of the distribution) increases with repeated plays. Thus, in the 10-play situation, one has a slight probability ($p = 0.00098$) to suffer a 10 times greater loss ($-\$1000$). Because of the differences in the range of losses and the EVs for single and multiple plays of a bet, researchers have often included comparison conditions in which EV and range of losses are equated for the two conditions, so that the influence of these factors can be isolated. Figure 1c shows the distribution of outcomes when payoffs are reduced by a factor equal to the number of plays. Note that Samuelson's objection does not apply to this situation where risk is clearly reduced, as evidenced by the much lower variance outcomes. This type of diversification strategy is a commonly used approach for reducing risk in a portfolio of assets.

Behavior for Samuelson's Bet

Several researchers have asked people to respond to bets that parallel the one Samuelson offered his colleague in order to consider the prevalence of this pattern of responding and evaluate rationales. In a study of college students, Wedell and Böckenholt [7] found that 79% of students refused a single play of the bet, but 44% of these were willing to play the bet 100 times. Benartzi and Thaler [8] surveyed undergraduates, graduate students, and coffee shop visitors with a problem that reduced the outcomes substantially from Samuelson's gamble and found only 34% refused the single-play version. Of these, roughly 44% were willing to play the bet 100 times, a similar conditional proportion as found by Wedell and Böckenholt. Keren [9] asked the 79% of participants, who refused to play Samuelson's bet one time, how many times it would have to be repeated before they were willing to play it. While 23% were willing to play it five times, 55% were willing to play it 100 times (a similar percentage as described above). Finally, Redelmeier and

Tversky [10] provided undergraduates with a bet similar to Samuelson's but with inflated amounts to win and lose. They found significantly fewer choices to play the bet once (43%) than five times (63%). In another sample, they asked participants to compare one play of the bet with five plays, five plays with six plays, and six plays with 12 plays. In each case, participants preferred the option of playing the bet more times. However, when asked whether after playing the gamble five times one would want to play it again, most participants refused, emphasizing the psychological difference between considering the set of gambles versus gamble one at a time. The results of these and other studies [11–18] indicate that the behavior of Samuelson's colleague to refuse a single play but endorse repeated plays of a gamble can be found in a substantial proportion of participants, although it may not be a majority response. This tendency may be greater for large outcome gambles, perhaps because of a higher refusal rate of the single gamble.

Reducing Decision Anomalies

It has long been known that human decision behavior often violates predictions of EU theory. To what extent is anomalous behavior found for single prospects reduced when participants evaluate repeated versions of those prospects? Keren and Wagenaar [19] investigated this question with respect to certainty and possibility effects, which Kahneman and Tversky [20] described as separable contributors to the Allais Paradox. In the certainty effect, a risky prospect A is compared to a certain (or near certain) prospect B, and then a control pair, A' and B', is created by reducing the probability of winning by a constant ratio. For example, A might be (0.50 to win \$250 else \$0) and B might be (1.00 to win \$100). Most people prefer the certain option, B, which means that the following inequality holds: $U(\$100)/U(\$250) < 0.50/1.00$. However, reducing each probability by a factor of 5 results in options A' (0.10 to win \$250 else \$0) and B' (0.20 to win \$100, else \$0). A majority of people prefer A' to B', which means that the following inequality holds: $U(\$100)/U(\$250) > 0.10/0.20$, a contradiction

of the choice of A over B. In the possibility effect, option probabilities are reduced by a constant ratio to create very low probability pairs that again create contradictory results. For example, one may prefer C (0.90 to win \$5000 else \$0) to D (0.45 to win \$12,000 else \$0), but prefer D' (0.01 to win \$12,000 else \$0) to C' (0.02 to win \$5000 else \$0).

Keren and Wagenaar [19] conducted two experiments in which participants chose between bets like those described above or the same types of bets represented as being played 10 or 100 times. For the unique, single-play gambles, they replicated both certainty and possibility effects. However, neither of these effects was significant for the repeated gambles. They concluded that different choice processes are invoked when considering the short-run unique gamble versus the long-run repeated gambles. In a follow-up, Keren [9] demonstrated a similar effect with gambles being played just once or five times. In these combined experiments, participants appeared to switch to a strategy of choosing the gamble with the higher EV when faced with multiple choices, consistent with results from Montgomery and Adelbratt [17] in which participants endorsed choosing on the basis of EV for multiple-play gambles but not for single-play gambles. The tendency for certainty and possibility effects to be reduced in the repeated-play situation implies that the choice process for repeated gambles is more consistent with EU theory than the process used for choosing single gambles.

Another violation of EU theory revolves around procedural invariance. Different preference elicitation methods can be used, such as choice, attractiveness ratings, minimum selling price, maximum buying price, and value matching. If the same utility and decision weighting processes underlie these different elicitation methods, then the preference ordering of risky prospects should be invariant across them. However, it has long been documented that preference order can be reversed by use of different methods for expressing preference [21]. In the classic response-based preference reversal, the same individual chooses between risky prospects and sets minimum selling prices for each. One prospect is referred to as a P-bet because

it has a relatively high probability to win a relatively small amount, such as a 0.90 chance to win \$2 else \$0. The other prospect is referred to as a \$-bet because one can win a relatively large amount but with a correspondingly smaller probability, such as a 0.10 chance to win \$20 else \$0. The typical finding is that the P-bet is preferred in choice, but the \$-bet is valued higher. Thus, people tend to choose the bet to which they assign a lower value.

Wedell and Böckenholt [22] examined whether the preference reversal phenomenon would obtain when gambles were represented as being played repeatedly. In both experiments, they found a significant reduction in preference reversals with an increase in the number of plays from one time to either 10 times or 100 times, although preference reversals were still significant for repeated-play conditions. Wedell and Böckenholt reported that the majority of subjects made fewer reversals in the multiple-play condition than in the single-play condition. When prompted to explain why they changed their pricing and choice behavior, the modal response was that the perceived chances of winning changed with increase in plays. Finally, note that Haisley *et al.* [23] demonstrated the tendency for choice to be more in line with EV for people purchasing actual lottery tickets (singly vs in groups of five), with the repeated-play version in this case leading to significantly fewer purchases.

A third violation of EU theory arises out of considerations of sources of uncertainty as described in the Ellsberg paradox [24]. Ellsberg found that when presented with a series of choices, the majority of people opt for the gamble with a known distribution of outcomes rather than an unknown distribution, the former representing uncertainty under risk and the latter uncertainty under ambiguity. This ambiguity aversion tendency was problematic, in that it led the majority to endorse choices that violated the independence axiom in EU theory. Liu and Colman [25] investigated the possibility that ambiguity aversion is reduced in the repeated-play case, and thus the potential violation of the independence axiom is likewise reduced. In two experiments in

which participants choose between risky and ambiguous options, they observed a strong reduction in ambiguity aversion for gambles represented as being played 100 times rather than once. These results then imply that decision makers tend to treat ambiguity and risk in a more equivalent manner when considering repeated-play gambles.

Medical Decisions

Redelmeier and Tversky [10,26] examined whether decisions of physicians would differ when considering a single instance versus aggregated instances. One study that compared aggregation across patients found that physicians were more willing to recommend a blood test when considering a single patient than a group of like patients (30% vs 17%). In another study that compared aggregation across time, physicians were more willing to recommend a risky medication when the term of the illness was expected to last many days than when it was to last a single day (42% vs 15%), even though the chronic nature of the disease made it difficult to justify treating the single instance differently from the repeated instances. However, DeKay and Kim [11] reviewed several studies that failed to replicate results of Redelmeier and Tversky [26]. They further suggested that choice differences for single and repeated situations depend on the perceived fungibility of the outcomes. Highly fungible monetary outcomes show large differences of the manipulation, but outcomes of low perceived fungibility, such as comparison across individuals, produce little effect of the single versus repeated perspective. In summary, the results in this area are mixed, with no simple pattern being observed across studies.

Investment Decisions

Investment decisions have a natural parallel to the structure of gambles, although it is less clear about the degree to which dependencies exist among investment options. Benartzi and Thaler [8] explored short- and long-run framing in a series of experiments that used hypothetical gambles and real retirement investments. One key finding from these studies was that the format in

which repeated gambles was presented was an important factor. While choices were more sensitive to EV for repeated than for single gambles, this difference was even more marked when tabular or graphic displays of the distribution of outcomes was shown (such as the displays in Fig. 1). This finding is not surprising when considering that limitations on cognitive resources would make it difficult for the average individual to accurately generate the probability distribution resulting from aggregation. (Consider an attempt at generating the outcome shown in Fig. 1b.) Benartzi and Thaler demonstrated in two additional studies that employees who were presented with the aggregate distribution over multiple years invested a much greater percentage of retirement funds in stock options than those given the one-year return rate (a 82% allocation to stocks vs a 41% allocation). Thus, when left to extrapolate consequences of repeated years of investment, people appear to be much more risk averse than when presented the resulting distribution of outcomes. Indeed, a study by Klos *et al.* [13] that examined investors' ability to judge various dimensions of the outcome distributions for investments and gambles found a decided advantage when the outcome distribution resulting from repeated instantiations was graphically represented.

While a number of studies have demonstrated greater acceptance of repeated or long-run investment strategies [8,12,18], Langer and Weber [14] demonstrated that the opposite effect could occur, depending on the structure of the investment. They replicated earlier work that utilized fairly large probabilities of moderate losses and then showed how gambles that included a low probability to lose a large amount were more likely to be endorsed for single plays than for repeated plays. They also demonstrated how both results were in line with prospect theory predictions.

THEORETICAL EXPLANATIONS

The clear differences in how many people respond to single and repeated instances of risky prospects can be explained by a

variety of theoretical mechanisms. The most prominent theoretical explanation has been derived from prospect theory and hinges around loss aversion. Kahneman and Lovallo [27] referred to this result as *myopic loss aversion* and showed how repeated prospects represented in their aggregated form largely eliminate loss aversion tendencies. This view of the phenomena implies that single and repeated gambles are essentially processed in the same way, although the latter requires editing into aggregate form. Others have referred to this as reflecting *narrow bracketing of outcomes* in the short run and *broad bracketing of outcomes* in the long run [18,23]. The take home message from this approach is not that there is a change in the valuation process, but rather that there is a change in the representation upon which valuation operates. For example, if we apply a simple loss aversion weighting scheme to Samuelson's bet in which losses are multiplied by a factor of 3, then one play of the bet is valued at $(0.5)(-100)(3) + (0.5)(200) = -50$ and so one would refuse to play it. However, applying this formulation to two plays of the bet results in a value of $0.25(-200)(3) + (0.50)(100) + (0.25)(400) = 0$, or indifference. According to this loss-averse weighting scheme, one would refuse a single play but choose three or more plays of the gamble. The key then is to aggregate across plays, or perhaps to see different investments as part of a broader portfolio across which one aggregates.

Other theoretical explanations focus on more distinct process differences between the situations, emphasizing shifting from qualitative to quantitative processing, a focus on aspiration levels, or on higher order features of distribution of outcomes related to variability, skewing, and rank [5–7,22]. Lopes [5,6] pointed out that EU theory's emphasis on one moment of the outcome distribution, the mean, may not lead to the wisest decisions. Other moments related to variability and skewing may be important, especially when some outcomes are catastrophic. It is possible that individuals use a qualitative comparison of outcomes to an aspiration level before proceeding to a more systematic valuation of the prospect [22]. If this is the case, then the

evaluation process would differ markedly for single- and multiple-play prospects because the multiple-play prospect would be more likely to exceed the aspiration level and proceed to a more integrative assessment. Consistent with this view are verbal reports justifying choice patterns [22] as well as evidence that risk assessment of single plays follows an additive integration pattern but that of multiple plays follows a multiplicative integration pattern [28]. Regardless of the mechanism, the extant literature is consistent with the view that people's evaluations of repeated risky prospects tend to conform more closely to normative standards, such as that described by EU theory, than their evaluations of risky prospects considered one at a time.

INTRODUCTION

Evolutionary computation (EC) techniques are stochastic algorithms whose search methods model some natural phenomena: genetic inheritance and Darwinian strife for survival. The idea behind evolutionary algorithms (EAs) is to do what nature does. Let us take rabbits as an example: at any given time there is a population of rabbits. Some of them are faster and smarter than other rabbits. These faster, smarter rabbits are less likely to be eaten by foxes, and therefore more of them survive to do what rabbits do best: make more rabbits. Of course, some of the slower, dumber rabbits will survive just because they are lucky. This surviving population of rabbits starts breeding. The breeding results in a good mixture of rabbit genetic material: some slow rabbits breed with fast rabbits, some fast with fast, some smart rabbits with dumb rabbits, and so on. And on the top of that, nature throws in a “wild hare” every once in a while by mutating some of the rabbit genetic material. The resulting baby rabbits will (on average) be faster and smarter than these in the original population because more faster, smarter parents survived the foxes. (It is a good thing that the foxes are undergoing similar process—otherwise the rabbits might become too fast and smart for the foxes to catch any of them). So the metaphor underlying EAs is that of natural evolution. In evolution, the problem each species faces

is one of searching for beneficial adaptations to a complicated and changing environment. The “knowledge” that each species has gained is embodied in the makeup of the chromosomes of its members. From the point of view of optimization, EC is a powerful stochastic zeroth order method (i.e., requiring only values of the function to optimize) that can find the global optimum of very rough functions. This allows EC to tackle optimization problems for which standard optimization methods (e.g., gradient-based algorithms requiring the existence and computation of derivatives) are not applicable. Moreover, most traditional methods are local in scope; thus, they identify only the local optimum closest to their starting point.

AN ALGORITHM

For the sake of clarity, we shall try to introduce a general framework, accounting as much as possible for most existing EAs.

Let the search space be a metric space E , and let F be a function $E \rightarrow \mathbb{R}$ called the *objective* function. The task of evolutionary optimization is to find the maximum of F on E (the case of minimization is easily handled by considering $-F$).

A *population* of size $P \in \mathbb{N}$ is a set of P *individuals* (points of E) not necessarily distinct. This population is generally initialized randomly (at time $t = 0$) and uniformly on E . Then the *fitness* of each individual is computed (on the basis of the values of the objective function); a fitness value is represented as a positive real number—the higher the number, the better the individual. The population then undergoes a succession of *generations*; the process is illustrated in Fig. 1.

Several aspects of the evolutionary procedure require additional comments:

- *Statistics and Stopping Criterion.* The simplest stopping criterion is based on the generation counter t (or on the number of function evaluations). However,

```

procedure evolutionary algorithm
begin
   $t \leftarrow 0$ 
  initialize population
  evaluate population
  while (not termination-condition) do
    begin
       $t \leftarrow t + 1$ 
      select individuals for reproduction
      apply variation operators
      evaluate newborn offspring
      select individuals for survival
    end
  end

```

Figure 1. The structure of an evolutionary algorithm.

it is possible to use more complex stopping criteria, which depend either on the evolution of the best fitness in the population along generations (i.e., measurements of the gradient of the gains over some number of generations), or on some measure of the diversity of the population.

- *Parental Selection.* Choice of some individuals that will generate offspring. Numerous selection processes can be used, either deterministic or stochastic. All are based on the fitness of the individuals. Depending on the selection scheme used, some individuals can be selected more than once. At that point, selected individuals give birth to copies of themselves (clones).
- *Application of Variation Operators.* To each one of these copies, some operator(s) are applied, giving birth to one or more offspring. The choice among possible operators is stochastic, according to user-supplied probabilities. These operators are always stochastic operators; it is common to distinguish between *crossover* (or *recombination*) and *mutation* operators:
 - crossover operators are operators from E^k into E , that is, some parents exchange genetic material to build up one offspring. In most cases, crossover involves two parents ($k = 2$), though more parents can be used.

- mutation operators are stochastic operators from E into E .

- *Evaluation.* Computation of the fitnesses of all newborn offspring. As mentioned earlier, the fitness measure of an individual is directly related to its objective function value.
- *Survival Selection.* Choice of which individuals will be part of next generation. The choice can be made either from the offspring only (in which case all parents “die”) or from both the offspring and the parents. In either case, this survival selection procedure can be deterministic or stochastic.

Sometimes the variation operators are defined on the same space as the objective function (called *phenotype space* or *behavioral space*); in other cases, an intermediate space is introduced (called *genotype space* or *representation space*). The mapping from the phenotype space in the genotype space is termed *coding*. The inverse mapping from the genotype space in the phenotype space is termed *decoding*. Genotypes undergo variation operators, and their fitness is evaluated on the corresponding phenotype. The properties of the coding mappings can greatly modify the global behavior of the EA. For more (implementational) details related to the structure outlined in Fig. 1 and further discussion on the above aspects of the evolutionary procedure, see Ref. 1.

AN EXAMPLE

In this section we provide an example (based on example given in Chapter 2 of Ref. 2) of action-steps of a standard genetic algorithm (GA)—the best-known paradigm within EAs—for a numerical optimization problem. These action-steps illustrate the general structure of EAs given in Fig. 1. Here, without any loss of generality, we assume the maximization problem where the objective function f takes positive values on its domain.

So let us suppose we wish to maximize a function of k variables, $f(x_1, \dots, x_k) : \mathbb{R}^k \rightarrow \mathbb{R}$. Suppose further that each variable x_i can

take values from a domain $D_i = [a_i, b_i] \subseteq \mathbb{R}$ and $f(x_1, \dots, x_k) > 0$ for all $x_i \in D_i$. We wish to optimize the function f with some required precision: suppose six decimal places for the variables' values are desirable.

It is clear that to achieve such precision each domain D_i should be cut into $(b_i - a_i) \cdot 10^6$ equal size ranges. Let us denote by m_i the smallest integer such that $(b_i - a_i) \cdot 10^6 \leq 2^{m_i} - 1$. Then, a representation having each variable x_i coded as a binary string of length m_i clearly satisfies the precision requirement. Additionally, the following formula interprets each such string:

$$x_i = a_i + \text{decimal}(\text{string}_2) \cdot \frac{b_i - a_i}{2^{m_i} - 1},$$

where $\text{decimal}(\text{string}_2)$ represents the decimal value of that binary string.

Now, each individual (in GA terminology, individuals are often called *chromosomes*) is represented by a binary string of length $m = \sum_{i=1}^k m_i$; the first m_1 bits map into a value from the range $[a_1, b_1]$, the next group of m_2 bits map into a value from the range $[a_2, b_2]$, and so on; the last group of m_k bits map into a value from the range $[a_k, b_k]$. A chromosome represents a potential solution to the problem.

To initialize the population, we can simply set some P number of chromosomes randomly in a bitwise fashion. However, if we do have some knowledge about the distribution of potential optima, we may use such information in arranging the set of initial (potential) solutions.

At each generation (while loop, see Fig. 1) we evaluate each chromosome (using the function f on the decoded sequences of variables), select new population with respect to the probability distribution based on fitness values, and alter the chromosomes in the new population by mutation and crossover operators. After some number of generations, when no further improvement is observed, the best chromosome represents an (possibly the global) optimal solution. Often we stop the algorithm after a fixed number of iterations depending on speed and resource criteria. For the selection process (selection of a new population with respect to the probability distribution based

on fitness values), a *roulette wheel* with slots sized according to fitness is used here; such a roulette wheel is constructed as follows:

- Calculate the fitness value $\text{eval}(v_i)$ for each chromosome v_i ($i = 1, \dots, P$).
- Find the total fitness of the population

$$F = \sum_{i=1}^P \text{eval}(v_i).$$

- Calculate the probability of a selection p_i for each chromosome v_i ($i = 1, \dots, P$):

$$p_i = \text{eval}(v_i) / F.$$

- Calculate a cumulative probability q_i for each chromosome v_i ($i = 1, \dots, P$):

$$q_i = \sum_{j=1}^i p_j.$$

The selection process is based on spinning the roulette wheel P times; each time we select a single chromosome for a new population in the following way:

- Generate a random (float) number r from the range $[0, 1]$.
- If $r < q_1$ then select the first chromosome (v_1); otherwise select the i -th chromosome v_i ($2 \leq i \leq P$) such that $q_{i-1} < r \leq q_i$.

Obviously, some chromosomes would be selected more than once. This is in accordance with the Schema Theorem (see the section titled "Comparison"): the best chromosomes get more copies, the average stay even, and the worst die off.

Now we are ready to apply the recombination operator, crossover, to the individuals in the new population. As mentioned earlier, one of the parameters of a genetic system is probability of crossover p_c . This probability gives us the expected number $p_c \cdot P$ of chromosomes which undergo the crossover operation. We proceed in the following way:

For each chromosome in the (new) population:

- Generate a random (float) number r from the range $[0,1]$;
- If $r < p_c$, select given chromosome for crossover.

Now we mate selected chromosomes randomly: for each pair of coupled chromosomes we generate a random integer number pos from the range $[1, m - 1]$ (m is the total length—number of bits—in a chromosome). The number pos indicates the position of the crossing point. Two chromosomes

$$(b_1 b_2 \dots b_{pos} b_{pos+1} \dots b_m) \text{ and} \\ (c_1 c_2 \dots c_{pos} c_{pos+1} \dots c_m)$$

are replaced by a pair of their offspring:

$$(b_1 b_2 \dots b_{pos} c_{pos+1} \dots c_m) \text{ and} \\ (c_1 c_2 \dots c_{pos} b_{pos+1} \dots b_m).$$

The next operator, mutation, is performed on a bit-by-bit basis. Another parameter of the genetic system, probability of mutation p_m , gives us the expected number of mutated bits $p_m \cdot m \cdot P$. Every bit (in all chromosomes in the whole population) has an equal chance to undergo mutation, that is, change from 0 to 1 or vice versa. So we proceed in the following way.

For each chromosome in the current (i.e., after crossover) population and for each bit within the chromosome:

- Generate a random (float) number r from the range $[0, 1]$;
- If $r < p_m$, mutate the bit.

Following selection, crossover, and mutation, the new population is ready for its next evaluation. This evaluation is used to build the probability distribution (for the next selection process), that is, for a construction of a roulette wheel with slots sized according to current fitness values. The rest of the evolution is just cyclic repetition of the above steps.

It is relatively easy to keep track of the best individual in the evolution process. It is customary (in GA implementations) to store

“the best ever” individual at a separate location; in that way, the algorithm would report the best value found during the whole process (as opposed to the best value in the final population)—this approach illustrates so-called *elitist* strategy.

HISTORICAL PARADIGMS

This section introduces the four historical paradigms that build what is today known as *evolutionary computation*.

Genetic Algorithms

In the canonical GA [3,4], the genotype space is $\{0, 1\}^n$. Note that the phenotype space can be any space, as long as it can be coded into bitstring genotypes. The parental selection is proportional selection (the best-known being the roulette wheel selection as discussed in the previous section): P random choices are made in the whole population, each individual having a probability proportional to its fitness of being selected. The crossover operators replace a segment of bits in the first parent string by the corresponding segment of bits from the second parent, and the mutation operator randomly flips the bits of the parent according to a fixed user-supplied probability. In the survival selection phase, all P offsprings replace all parents (also known as *generational survival*). The best fitness in the population can thus decrease: the original GA strategy is not elitist.

However, it rapidly became clear that the genotype space can be almost any space, as long as some crossover and mutation operators are provided [2,5]. Moreover, proportional selection has been gradually replaced by comparison-based selections, from *ranking* (the selection is performed on the rank of the individuals rather than on their actual fitness), or *tournament* selection (one selects the best individual among a uniform choice of T individuals, T ranging from two to some small proportion of the population size)—see Ref. 6 for a discussion on these selection methods. Finally, most users use the elitist variant of survival selection, in which the best individual of generation t is included in generation $t + 1$, whenever the best fitness value in the population decreases.

Evolution Strategies

Evolution strategies (ESs) [7,8] have been designed as *parametric optimization* algorithms, that is, optimizing functions of floating-point variables. The original ES handles a “population” made of a single individual given as a real-valued vector. This individual undergoes a Gaussian mutation: addition of zero-mean Gaussian variable of standard deviation σ to each of the real variables. The fittest from the parent and the offspring becomes the parent of next generation. The critical feature is the choice of parameter σ : Originally, the so-called 1/5 thumb rule [i.e., when more than 1/5 mutation are successful (respectively unsuccessful), increase (respectively decrease) σ] [7].

ES then evolved into population-based algorithms [9], termed (μ, λ) – ES or $(\mu + \lambda)$ – ES: μ parents generate λ offspring. (There is no parental selection, i.e., every parent produces λ/μ offspring on average). Moreover, the survival selection is deterministic, that is, the best μ individuals become the parents of the next generation, chosen among the $\mu + \lambda$ parents plus offspring in the elitist $(\mu + \lambda)$ – ES scheme, or among the λ offspring in the nonelitist (μ, λ) – ES scheme (with $\lambda \geq \mu$).

The main operator remains mutation, generalized into multivariate Gaussian mutation, that is, defined by a full covariance matrix C and a scaling factor σ , also called the *step-size* mutation. In the 1990s, the powerful paradigm of *self-adaptive mutation* was the rule: C and σ were added to the description of the individuals, and undergo mutation as well. The recent trend is to adapt C and σ based on the history of the evolution, leading to the state-of-the-art algorithm of *covariance matrix adaptation—evolution strategy* (CMA-ES) [10,11]. CMA-ES is almost parameter-free: it uses a $(\lambda/2, \lambda)$ – ES survival selection, where the parameter λ is chosen as $4 + \lfloor 3 \log(n) \rfloor$ [10], and increased in case of highly multimodal functions [11].

Evolutionary Programming

Evolutionary programming (EP) is one of the oldest EAs, originally proposed to evolve finite state machines [12]. As in ESs, there is no parental selection, and every individual in

the population generates one offspring. Moreover, the only evolution operator is mutation. Survival selection is what is today called a $(P + P)$ – ES, that is, the best P individuals among parents and offspring become the parents of the next generation.

As in the field of GAs, further works rapidly generalized the approach to handle any search space, still emphasizing the use of mutation as the only operator [13]. Several variants were then introduced, from stochastic survival selection to self-adaptive mutations (similar to the ones from ESs, though discovered completely independently [14]).

Genetic Programming

Genetic programming (GP) as a method for evolving computer programs first appeared as an application of GAs to tree-like structures [15]. Original GP evolves tree structures representing LISP-like S-expressions. The strength of this representation is that a closed crossover operator can easily be defined: by swapping subtrees between two valid S-expressions, one always gets a valid S-expression. Koza’s original work used a steady-state GA evolutionary mechanism [16]: a parent is selected by tournament (of size two to seven typically), and generates an offspring by crossover only. The offspring is then put back in the population using a reverse tournament: T individuals are uniformly chosen, and the one with the worst fitness gets replaced by the newborn offspring.

Since then, most published work considered mutation also. Further, several variants of tree-based GP have been proposed (e.g., linear GP [17], cartesian GP [18], push GP [19]). At present, GP is viewed more generally as program evolution [20].

MODERN TRENDS: HYBRID METHODS

Many researchers further modified EAs by “adding” some problem-specific knowledge to the algorithm. Several papers have discussed initialization techniques, different representations, decoding techniques (mapping from genetic representations to phenotypic representations), and the use of heuristics for

variation operators. Davis [21] wrote (in the context of classical, binary GAs):

“It has seemed true to me for some time that we cannot handle most real-world problems with binary representations and an operator set consisting only of binary crossover and binary mutation. One reason for this is that nearly every real-world domain has associated domain knowledge that is of use when one is considering a transformation of a solution in the domain [...]. I believe that genetic algorithms are the appropriate algorithms to use in a great many real-world applications. I also believe that one should incorporate real-world knowledge in one’s algorithm by adding it to one’s decoder or by expanding one’s operator set.”

Such hybrid/nonstandard systems enjoy a significant popularity in the EC community. Very often these systems, extended by the problem-specific knowledge, outperform other classical evolutionary methods as well as other standard techniques. For example, a system, Genetic-2N [2] constructed for the nonlinear transportation problem used a matrix representation for its chromosomes, a problem-specific mutation (main operator, used with probability 0.4), and arithmetical crossover (background operator, used with probability 0.05). It is hard to classify this system: it is not really a GA, since it can run with a mutation operator only without any significant decrease of the quality of results. Moreover, all matrix entries are floating-point numbers. It is not an ES, since it did not use Gaussian mutation, nor did it encode any control parameters in its chromosomal structures. Clearly, it has nothing to do with GP and very little (just matrix representation) with EP approaches. It is just an EC technique aimed at a particular class of problems.

COMPARISON

Many papers have been written on the similarities and differences between these approaches [9,13,22]. Clearly, these similarities and differences can be discussed from different perspectives.

- *The Representation Issue.* Original GAs, ESs, and EP address only bitstrings,

real numbers, and finite state machines, respectively. However, recent tendencies indicate that this is not a major difference. Moreover, it is still far from trivial to select appropriate variation operators for the chosen representation and the objective function, also known as the *fitness landscape* [2,5].

- *The Usefulness of Crossover.* According to the Schema Theorem [3,4], GAs’ main strength comes from the crossover operator: better and better solutions are built by exchanging *building blocks* from partially good solutions previously built, in a bottom-up approach. The mutation operator is then considered as a background operator. On the other hand, the philosophy behind EP and ESs is that such building blocks might not exist, at least for most real-world problems. Also some experimental results contradict the building block hypothesis; for example, uniform crossover [23] is very disruptive of short schemata whereas one- and two-point crossover are more likely to conserve short schemata and combine their defining bits in offspring. This top-down view considers that selective pressure plus genotypic variability brought by mutation are sufficient. This discussion on significance of the crossover has been going on for a long time. However, even when crossover is experimentally demonstrated beneficial to evolution, it could be because it acts like a large mutation [24]. Yet another example of the duality between crossover and mutation comes from GP’s history: the original GP algorithm [15] used only crossover, with no mutation at all, with very large population size: the rationale is that all building blocks that are necessary to represent at least one sufficiently good solution are already present in the initial population, and only need to be recombined.
- *Mutation Operators.* Whereas the usefulness of crossover has been heavily discussed, that of mutation is acknowledged by all trends (with the historical exception of Koza’s work in GP—see the

section titled “Genetic Programming”). Indeed, mutation is the only operator that can reintroduce *diversity* in the population, as crossover is *de facto* limited by the current population. From a theoretical point of view, only mutation can guarantee the ergodicity of the stochastic process (i.e., that all points of the search space can be reached whatever the current population). However, the way mutation operators are applied differ from one paradigm to another, and should be closely linked to the types of selection that are used. Traditional GAs use a low mutation rate, that is, the average number of bits that are flipped remains small (though it can take large values, with very small probabilities). Because all offspring replace all parents without competition, high mutation rates would totally prevent any convergence to any optimal solution, as mutation gets more and more destructive as the population contains better and better solutions. Within ESs, on the other hand, all individuals undergo mutation, and only the strength of the mutation is varied (e.g., the standard deviation of the Gaussian mutation, in one dimension). Together with the fact that several offspring are generated from each parent, this nevertheless still allows the algorithm to converge. Furthermore, it can converge to any arbitrary precision provided the mutation strength is decreased accordingly: this was first demonstrated by self-adaptive ES [8,25], and proved right for CMA-ES as well [10]. Indeed, adaptive and self-adaptive mutations can have a significant impact only when all individuals undergo mutation. Furthermore, it also requires some property of the mutation with respect to the fitness function called the *strong causality principle* emphasized in Ref. 7: mutation should be parameterized in such a way that small mutations have small effects on the fitness. This property is not specific to floating-point optimization, and should be kept in mind when designing mutation operators for a particular

representation. In particular, this property is not true when floating-point numbers are encoded into binary strings (as is the case in traditional style GAs).

- *The Selection Mechanisms.* They range from the totally stochastic fitness proportional parental selection of GAs with generational survival, to the deterministic (μ, λ) survival selection of ES, through the stochastic, but elitist (i.e., preserving the best), tournament-based survival step of EP and the steady-state scheme used in GP. Though some studies have been devoted to selection mechanisms [6], the choice of both selection steps for a given problem (fitness representation operators) is still an open question (and is very likely to be problem-dependent).

The current trend in the EC community is to mix up all these features on a very pragmatic basis, trying to best fit the application at hand: some ESs applications deal with discrete or mixed real-integer spaces [22], the early arguments [26] against the dogma “binary is the best” have diffused in the community, and the Schema Theorem has been extended to any representation [5]. Moreover, most ESs (including CMA-ES) use some crossover operator, mutation has been added to GP, and so on. And the different selection operators are more and more being used now by the whole community.

On the other hand, such hybrid algorithms, by getting away from the simple original algorithms, also escape the few available theoretical results, and EAs can today only rely on successful applications (see the section titled “Application Areas”) to demonstrate their usefulness as general-purpose optimization algorithms.

THEORETICAL RESULTS

Theoretical studies of EAs can be roughly categorized into three different types.

- An EA can be viewed as a Markov chain in the space of populations, as the population at time $t + 1$ only depends on

the population at time t . The full theory of Markov chains can then be applied. Some asymptotic results were obtained for general EAs [27], and for more focused algorithms [28], but for very specific and simple functions. Stronger results (convergence in finite time) were obtained using the powerful Friedlin—Wentzell theory [29] for very general functions, but a specific algorithm. However, those results have limited practical consequences as the real-world environment often requires short response times.

- The specific characteristics of ESs allowed precise theoretical studies on the *sphere function*, that is, the quadratic function. Early theoretical studies by the ES pioneers resulted in Rechenberg's 1/5th rule [7], and in Schwefel's first self-adaptive ES [8]. These works were later pursued in Schwefel's group in Dortmund, with the precise study of the so-called *progress rate*, that is, the improvement from one step of the algorithm to the next, by Beyer [25]. Finally, these results that had been obtained asymptotically for very high dimensions, have been rigorously justified in any dimension. In particular, all numerical values for optimal settings have been shown to actually be optimal, with the help of the theory of irreducible Harris recurrent Markov chains [30,31].
- Last, but not least, the classical Algorithm Complexity Theory has been used to study EAs on discrete spaces. The pioneer of this approach was Ingo Wegener, and most works in this area come from his group in Dortmund (and some spin-off groups led by his former PhD students). Here the algorithms under study are simple but actual algorithms (and they get progressively less "simple" every year), while the fitness functions are simple functions or classes of functions. Results range from effective complexity for hitting the optimum of linear Boolean functions with a $(1+1)$ -ES [32] to general

bounds for stochastic search algorithms in generic black box scenarios [33].

However, one should keep in mind that all the above theoretical analyses address some simple models of EAs. As stated earlier, the modern trends of EC gave birth to algorithms working on poorly structured search spaces (see next section), or hybrid algorithms, for which no theory is applicable at the moment.

APPLICATION AREAS

It is widely acknowledged that EC theory lags far behind practice. Indeed, lessons from successful applications are one of the main driving forces of EA research today. Several edited books are devoted to applications of EAs (e.g., see the recent edition [34]), and almost every event related to EAs has its own special session dedicated to applied works, and their proceedings provide a wide overview of actual applications [e.g., see several special sessions of the annual *IEEE Congress on Evolutionary Computation* (CEC), and the *Real-World Application* track run every year during the *ACM Genetic and Evolutionary Computation Conference* (GECCO)].

This section will quickly survey the preferred domains of application of EAs, and the different subdomains will be distinguished according to the type of search space they involve.

Combinatorial Optimization

Hard combinatorial optimization problems (NP hard, NP complete) involve huge discrete search spaces, and have been studied extensively by the operational research community. Two different situations should be considered: academic benchmark problems and large real-world problems.

As far as benchmark problems are concerned, it is now commonly acknowledged that pure EAs alone cannot compete with operations research (OR) methods (see all papers about combinatorial optimization in Ref. 35, for instance). However, in the last decade, hybrid algorithms termed *genetic local search*, or *memetic algorithms*, where

the EA searches the space of local optima with respect to some OR heuristic, have obtained the best-so-far results on a number of such benchmark problems [36,37].

The situation is slightly different for real-world problems: “pure” OR heuristics generally do not directly apply, and OR methods have to take into account problem specificities. This is true of course for EAs, and there are many success stories where EAs, carefully tuned to the problem at hand, have been very successful, as for instance in the broad area of scheduling [38,39]. A few commercial applications of EAs were also reported; some of them resulted in a significant return on investment [40]. However, these applications also required forecasting components, resulting in hybrid adaptive business intelligence systems [41].

Parametric Optimization

The optimization of functions with floating-point variables has been thoroughly studied by practitioners, and many very powerful methods exist. Though the most well-known methods address linear convex problems, there are many other cases that can be handled successfully [42]. However, the recently developed CMA-ES [10,11] can be viewed as the leading EA in the continuous domain, outperforming the best methods from both deterministic and stochastic domains for highly multimodal, irregular, ill-conditioned, and nonseparable functions. An impressive list of applications of CMA-ES is maintained on its inventor’s web page [43].

The situation is different when dealing with multiobjective problems: multiobjective evolutionary algorithms (MOEAs) are the only ones that can produce a set of best possible compromises (the *Pareto set*), and have recently received increased attention. MOEAs use the same variation operators as standard EAs, but the Darwinian components are modified to take into account the multivalued fitness [44,45]. Note that MOEAs are discussed in the section titled “Parametric Optimization” because prominent application results have been obtained in that area [46], but can be applied on any search space, as only the Darwinian part

of the algorithm is different from that of a single-objective EA.

Mixed Search Spaces

Mixed search spaces involve different types of variables, generally both continuous and discrete, and EAs are flexible enough to handle such search spaces easily. Once variation operators are known for continuous and discrete variables, constructing variation operators for mixed individuals is straightforward: crossover, for instance, can either exchange values of corresponding variables, or use the variable-level crossover operator. Many problems have been easily handled that way, like the optical filter optimization [47,48], where one is looking for a number of layers, the unknown being the layer thickness (continuous variable) and the material the layer is made of (discrete variable). Furthermore, some platforms now exist that help the non-EC experts to implement generic EAs for a given problem involving different types of mixed search spaces, requiring only a structured description of potential solutions, and of course a routine to compute the fitness of those candidate solutions [49].

Artificial Creativity

A very promising area of application of EAs, where EAs can be much more than yet another optimization method, is that of design, where the ability of EAs to handle almost any search space allows programmers (and artists!) to unveil their wildest ideas. The idea of component-based representations can boost innovation in structural design [50,51], architecture [52], as well as in many other areas including art [53]. But the most original idea in that direction is that of embryogenesis: the genotype is a program, and the phenotype is the result of applying that program to “grow an embryo”; the fitness of the genotype (the program) is obtained by testing that phenotype in a real situation. Such an approach has already led to astonishing results in analog circuit design, for instance, [54]—though exploring a huge search space (a space of programs) implies a heavy computational cost. Note that these results were achieved using GP (see the

section titled “Genetic Programming”), using both crossover and mutation, and a huge (distributed) population as well. Nevertheless, we firmly believe that great achievements can come from original ideas related to these developmental approaches [55].

CONCLUDING REMARKS

Natural evolution can be considered as a powerful problem solver, which evolved *Homo sapiens* from chaos, in only a couple of billion years. Computer-based evolutionary processes can also be used as efficient problem solvers for optimization, constraint handling, machine learning, and modeling tasks. Furthermore, many real-world phenomena from the study of life, economy, and society can be investigated by simulations based on evolving systems. Last but not least, evolutionary art and design form an emerging field of applications of the Darwinian ideas. We expect that computer applications based on evolutionary principles will gain popularity in the coming years in science, business, and entertainment.

An interesting question, which is being raised from time to time, asks for guidance on the types of problems for which evolutionary methods are more appropriate than, say, standard OR methods. From our perspective, the best answer to this question is given in a single phrase: *complexity*. Let us explain.

Real-world problems are usually difficult to solve for several reasons, and include [1] the following.

- The number of possible solutions is so large as to forbid an exhaustive search for the best answer.
- The evaluation function that describes the quality of any proposed solution is noisy or varies with time, thereby requiring not just a single solution but an entire series of solutions.
- The possible solutions are so heavily constrained that constructing even one feasible answer is difficult, let alone searching for an optimum solution.

Naturally, this list could be extended to include many other possible obstacles. For

example, we could include noise associated with our observations and measurements, uncertainty about given information, and the difficulties posed by problems that have multiple and possibly conflicting objectives (which may require a set of solutions rather than a single solution). All these reasons are just various aspects of the complexity of the problem.

Note that every time we solve a problem we must realize that we are in reality only finding the solution to a *model* of the problem. All models are a simplification of the real world—otherwise they would be as complex and unwieldy as the natural setting itself. Thus, the process of problem solving consists of two separate general steps: (i) creating a model of the problem, and (ii) using that model to generate a solution:

Problem $\Rightarrow$ Model $\Rightarrow$ Solution.

Note that the “solution” is only a solution in terms of the model. If our model has a high degree of fidelity, we can have more confidence that our solution will be meaningful. In contrast, if the model has too many unfulfilled assumptions and rough approximations, the solution may be meaningless, or worse.

So, in solving real-world problems there are at least two ways to proceed:

1. we can try to simplify the model so that traditional methods might return better answers or
2. we can keep the model with all its complexities, and use nontraditional approaches, to find a near-optimum solution.

In other words, the more complex the problem (e.g., size of the search space, evaluation function, noise, constraints), the more appropriate it is to use a nontraditional method, like EAs. Anyway, it is difficult to obtain a precise solution to a problem because we either have to approximate a model or approximate the solution. And a large volume of experimental evidence shows that this latter approach can often

be used to practical advantage (see, e.g., www.SolveITSoftware.com).

One can also look at EAs from a broader perspective of population-based methods, where a set of potential solutions is being processed in parallel. Apart from EAs, there are other population-based approaches that have been proposed over the last 20 years; these include differential evolution [56], artificial immune systems [57], particle swarm optimization [58], ant colony optimization [59], and cultural algorithms [60].

EVOLUTIONARY GAME THEORY AND EVOLUTIONARY STABILITY

ROSS CRESSMAN
Department of Mathematics,
Wilfrid Laurier University,
Waterloo, Ontario, Canada

Evolutionary game theory developed as a means to predict the expected distribution of individual behaviors in a biological system with a single species that evolves under the influence of natural selection [1,2]. The theory's predictions correspond to intuitive static solutions (e.g., the ESS of Definition 1 below) of the game formed through fitness (i.e., payoff) comparisons of different behaviors (i.e., strategies). The ESS then provides a definition of stability in the biological system that does not rely on an explicit dynamical model of behavioral evolution. When such a solution exhibits evolutionary stability (i.e., when it is a dynamically stable equilibrium of the evolving population), the detailed analysis of the underlying dynamical system can be ignored. Instead, it is the heuristic static conditions of evolutionary stability that become central to understanding behavioral evolution when complications such as genetic, spatial, and population size effects are added to evolutionary dynamics.

This biological perspective of evolutionary game theory [and especially its relationship to dynamic stability when the evolutionary system is modeled by the deterministic replicator equation (see Definition 1 below)] has been summarized in several survey monographs and books [3–7]. Evolutionary game theory has also become a standard method to analyze games that model human interactions between players that can be individuals or other economic entities such as firms or even nations [8,9]. Biological behavioral patterns then correspond to a player's strategy and the fitness generated when patterns interact become the strategy's

payoff. Evolutionary stability can then be interpreted as a strategic situation which has achieved an equilibrium in the sense of dynamical systems.

A fundamental result is that, at evolutionary stability of a behavioral distribution, no individual in the population can increase its fitness by unilaterally changing strategy. That is, evolutionary stability implies Nash equilibrium (NE) behavior: a result that has come to be known as (one aspect of) the folk theorem of evolutionary game theory [10,11]. However, as we will see, evolutionary stability requires more than NE. Thus, it can be viewed as an NE refinement or equilibrium selection technique. It is in this latter capacity that evolutionary game theory initially gained prominence in the economic literature when applied to rational decision making in classical noncooperative, symmetric games in either normal form or extensive form (See Refs 12, 13 and the references therein). These evolutionary games, that have linear payoffs and finitely many strategies, often consider other deterministic or stochastic evolutionary dynamics besides the replicator equation since these are thought to better represent decision making applied to economic or learning models [10,13–20]. The theory has been extended to nonsymmetric games that model two (or more) species and, more recently, to population games with nonlinear payoffs and/or a continuum of strategies [9,11,21].

Evolutionary stability is most clear when individuals in a single species can use only two possible strategies, denoted as p^* and p to match notation used later in this article, and payoffs are linear. Suppose that $\pi(p, \hat{p})$ is the payoff to a strategy p user against strategy $\hat{p}$ (or, in biological terms, the fitness of an individual using p in a random pairwise interaction in a large population exhibiting behavior $\hat{p}$). Then, an individual in a monomorphic population where everyone uses p^* cannot improve its fitness by switching to p if

$$\pi(p, p^*) \leq \pi(p^*, p^*) \quad \text{NE condition.} \quad (1)$$

If p does as well as p^* against p^* (i.e., if $\pi(p, p^*) = \pi(p^*, p^*)$), then evolutionary stability requires the extra condition that p^* must do better than p against p . That is,

$$\pi(p, p) < \pi(p^*, p) \text{ if } \pi(p, p^*) = \pi(p^*, p^*) \\ \text{stability condition.} \quad (2)$$

To see why both these conditions are necessary for dynamic stability, under the assumption of Maynard Smith [22] that “like begets like,” the per capita change in the number of individuals using strategy p is its expected payoff. This leads to the following continuous-time invasion dynamics of a resident monomorphic population p^* by a small proportion ε of mutants using p (it is the replicator equation for the game with two strategies, p and p^*).

$$\begin{aligned} \dot{\varepsilon} &= \varepsilon[\pi(p, \varepsilon p + (1 - \varepsilon)p^*) - \pi(\varepsilon p + (1 - \varepsilon)p^*, \\ &\quad \varepsilon p + (1 - \varepsilon)p^*)] \\ &= \varepsilon(1 - \varepsilon)[\pi(p, \varepsilon p + (1 - \varepsilon)p^*) \\ &\quad - \pi(p^*, \varepsilon p + (1 - \varepsilon)p^*)] \\ &= \varepsilon(1 - \varepsilon)[(1 - \varepsilon)(\pi(p, p^*) - \pi(p^*, p^*)) \\ &\quad + \varepsilon(\pi(p, p) - \pi(p^*, p))]. \end{aligned} \quad (3)$$

If p^* is a strict NE (i.e., the inequality in (Eq. 1) is strict), then $\dot{\varepsilon} < 0$ for all positive ε that are close to 0 since $(1 - \varepsilon)(\pi(p, p^*) - \pi(p^*, p^*))$ is the dominant term corresponding to the common interactions against p^* . Furthermore, if this term is 0 (i.e., if p^* is not strict), we still have $\dot{\varepsilon} < 0$ from the stability condition of Equation (2) corresponding to the less common interactions against p . Conversely, if $\dot{\varepsilon} < 0$ for all positive ε that are close to 0, then p^* satisfies conditions (1) and (2). Thus, the resident population p^* (i.e., $\varepsilon = 0$) is locally asymptotically stable¹

under Equation (3) (i.e., there is evolutionary stability at p^* under the replicator equation) if and only if p^* satisfies Equations (1) and (2). In fact, evolutionary stability occurs at such a p^* in these two-strategy games for any evolutionary dynamics whereby the proportion (or frequency) of users of strategy $\hat{p}$ increases if and only if its expected payoff is higher than that of the alternative strategy.

Moreover, if conditions (1) and (2) hold for all other alternative strategies in a symmetric game with finitely many pure strategies and linear payoffs, then p^* is an ESS (i.e., an *evolutionarily stable strategy*) according to John Maynard Smith in his influential book, *Evolution and the Theory of Games* [22, p. 14]. These concise mathematical conditions translate his informal definition (p. 10) as “a strategy such that, if all members of the population adopt it, then no mutant strategy could invade the population under the influence of natural selection.” This article begins with a thorough discussion of the connection between the static ESS conditions and evolutionary stability for these symmetric normal-form games. The complex relationship between these concepts here serves as the prototype of evolutionary game theory.

Additional complications in this relationship that arise in each of several types of more general games are briefly considered in the remainder of the article. Throughout, the biological perspective and terminology of evolutionary game theory is emphasized. The concepts and results in this interpretation can all be translated into a form more typical for games involving humans. In fact, it is this reinterpretation of the theory of biological evolutionary games as economic evolutionary games (and vice versa) that has historically fed the explosive growth of evolutionary game theory over the past thirty years.

¹Clearly, the unit interval $[0, 1]$ is (forward) invariant under the dynamics of Equation (3) (i.e., if $\varepsilon(t)$ is the unique solution of Equation (3) with initial value $\varepsilon(0) \in [0, 1]$, then $\varepsilon(t) \in [0, 1]$ for all $t \geq 0$). The rest point $\varepsilon = 0$ is (neutrally) stable if, for every

neighborhood U of 0 relative to $[0, 1]$, there exists a neighborhood V of 0 such that $\varepsilon(t) \in U$ for all $t \geq 0$ if $\varepsilon(0) \in V \cap [0, 1]$. It is *attracting* if, for some neighborhood U of 0 relative to $[0, 1]$, $\varepsilon(t)$ converges to 0 whenever $\varepsilon(0) \in U$. It is *(locally) asymptotically stable* if it is both stable and attracting.

EVOLUTIONARY GAME THEORY FOR SYMMETRIC NORMAL-FORM GAMES

In an evolutionary game with symmetric normal form, the population consists of individuals who must all use one of finitely many (say n) possible behaviors at any particular instant in time. These strategies are denoted as e_i for $i = 1, \dots, n$ and $S \equiv \{e_1, \dots, e_n\}$ is called the *pure strategy set*. An individual may also use a mixed strategy in $\Delta^n \equiv \{p = (p_1, \dots, p_n) \mid \sum_{i=1}^n p_i = 1, p_i \geq 0\}$, where p_i is the proportion of the time this individual uses pure strategy e_i . If population size is large and the components of $\hat{p} \in \Delta^n$ are the current frequencies of strategy use in the population (i.e., $\hat{p}$ is the population state), then the payoff of an individual using p in a random pairwise interaction is given explicitly through the bilinear payoff function of the (two-player) symmetric normal-form game, $\pi(p, \hat{p}) \equiv \sum_{i,j=1}^n p_i \pi(e_i, e_j) \hat{p}_j$, where as before $\pi(e_i, e_j)$ is the payoff to e_i against e_j .²

The following definition generalizes the ESS concept and the replicator equation developed for the two-strategy game in the introductory section to games with finitely many strategies.

Definition 1. Suppose S is the pure-strategy set for a symmetric normal-form game.

- (a) $p^* \in \Delta^n$ is an *ESS* if it satisfies conditions (1) and (2) for all $p \in \Delta^n$ with $p \neq p^*$.
- (b) The (pure-strategy) *replicator equation*, which is invariant on Δ^n , is given by

$$\dot{p}_i = p_i (\pi(e_i, p) - \pi(p, p)) \quad \text{for } i = 1, \dots, n. \quad (4)$$

²If e_i is represented by the i^{th} unit column vector in R^n and $\pi(e_i, e_j)$ is entry A_{ij} in an $n \times n$ payoff matrix A , then $\pi(p, \hat{p})$ is the inner product $p \cdot A\hat{p}$ of the two column vectors p and $A\hat{p}$. For this reason, symmetric normal form games are often called *matrix games* with payoffs given in this latter form.

The replicator equation emerges from the biological interpretation [23] of fitness as reproductive success (i.e., the individual's expected number of offspring). It has the intuitive property that strategies with higher current payoff increase in relative frequency (i.e., become more common). For two-strategy games, the replicator equation then increases the frequency of the better strategy. One of the early successes of evolutionary game theory is the following result [4,23].

Theorem 1. *If $p^* \in \Delta^n$ is an ESS, then p^* is asymptotically stable with respect to the replicator equation (Eq. 4).*

That is, evolutionary stability of an ESS holds for the replicator equation for multiple pure strategies and not only for the invasion of p^* by a subpopulation using a single mutant strategy p . The converse of Theorem 1 is true when there are two pure strategies (i.e., $n = 2$) but not in general. In fact, there already exist non-ESS strategies p in three-strategy symmetric normal-form games (i.e., for $n = 3$) that are asymptotically stable under Equation (4) (such strategies p must be NE by the folk theorem). To illustrate this, consider the payoff matrix

$$\begin{array}{c} R \\ P \\ S \end{array} \begin{bmatrix} 0 & 2 - \alpha & 4 \\ 6 & 0 & -4 \\ -2 & 8 - \alpha & 0 \end{bmatrix}, \quad (5)$$

with parameter α . For $2 < \alpha < 8$, this is a generalized Rock–Paper–Scissors (RPS) game since it exhibits cyclic dominance (i.e., P strictly dominates in the two-strategy $\{R, P\}$ game, S strictly dominates in the two-strategy $\{P, S\}$ game, and R strictly dominates in the two-strategy $\{R, S\}$ game). For $-16 < \alpha < 14$, there is a unique symmetric NE; namely, $p^* = (28 - 2\alpha, 20, 16 + \alpha)/(64 - \alpha)$. This is an ESS if and only if $-16 < \alpha < 3.5$ but it is globally asymptotically stable under Equation (4) if and only if $-16 < \alpha < 6.5$. That is, p^* has evolutionary stability with respect to the replicator equation but is not an ESS for $3.5 \leq \alpha < 6.5$. On the other hand, p^* is asymptotically stable under all (mixed-strategy) replicator equations for which some

distribution of these mixed strategy types have average strategy p^* (i.e., p^* is *strongly stable* according to Refs 6 and 15) if and only if p^* is an ESS. Thus, an ESS is equivalent to evolutionary stability with respect to mixed-strategy replicator equations.

There are several important classes of symmetric games that always have an ESS. One such class consists of all matrix games with a symmetric payoff matrix (i.e., $\pi(\hat{p}, p) = \pi(p, \hat{p})$ for all $p, \hat{p} \in \Delta^n$) for which the quadratic function $\pi(p, p)$ on Δ^n has an isolated local maximum.³ In fact, p^* is an ESS if and only if p^* is an isolated local maximum. Moreover, only the ESSs have evolutionary stability with respect to the replicator equation. These results follow from the Fundamental Theorem of Natural Selection [4] that asserts population mean payoff $\pi(p, p)$ is strictly increasing except at equilibrium when fitness is modeled by a single diploid locus with finitely many alleles. It was recognized early on [25] that the replicator equation is then the selection equation of population genetics that models the evolution of allele frequencies at this locus when the viability of genotype $A_i A_j$ equals $\pi(e_i, e_j)$. In the game-theoretic context, these games are known as *partnership games* [4], *doubly symmetric games* [13], or *common interest games* [9].

Another important class that has a unique ESS is the set of *strictly stable games*, which are games with $\pi(p - \hat{p}, p - \hat{p}) < 0$ for all $p \neq \hat{p}$ in Δ^n [9]. Any strictly stable game has a unique NE and this strategy is an ESS that is globally asymptotically stable with respect to

the replicator equation. All games with a completely mixed ESS p^* (i.e., p^* is in the interior of Δ^n) are strictly stable [15]. So are war-of-attrition games with an increasing cost of waiting and a finite set of waiting times [10] as well as many congestion games that model traffic flow in transportation networks [9]. Single-species habitat selection games (with linear payoffs) are also strictly stable [26] with unique ESS more commonly known as the *ideal free distribution* (IFD) [27].

There are also games that have multiple ESSs. The two-strategy symmetric coordination game

$$\begin{matrix} e_1 & \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix} \\ e_2 & \end{matrix}$$

is the most elementary example. This has three symmetric NE; namely, both pure strategies as well as the mixed strategy $p^* = (\frac{2}{3}, \frac{1}{3}) \in \Delta^2$. Only the pure strategies are ESSs (they are also the only asymptotically stable strategies). Thus, equilibrium selection via evolutionary stability discards the unstable mixed NE, leaving both pure strategies as possible evolutionary outcomes. Stochastic stability [14, 28, 29] can then be used to select the ESS e_2 since it is the risk-dominant [30] strict NE. In terms of deterministic evolutionary dynamics, e_2 is selected since it has the larger basin of attraction (i.e., the set of initial conditions that evolve to e_2 is a larger interval than the interval that evolves to e_1). Stochastic effects, due to infrequent (but ongoing) individual experimentation of the other strategy, then make it more difficult for the population to shift from the larger basin of attraction to the smaller one than vice versa, implying the system will evolve near e_2 .

Unfortunately, there are many games that have no ESS or asymptotically stable NE.⁴ In particular, the standard normal form of an extensive form game often has no ESS since every such ESS must be pervasive (i.e., it must reach every information set when played against itself) and can have

³If the quadratic function $\pi(p, p)$ has a local maximum p on Δ^n that is not isolated, then the maximal connected set of local maxima E containing p is an ESSet (evolutionarily stable set; (i.e., every $p^* \in E$ is a NE and, if $\pi(p, p^*) = \pi(p^*, p^*)$ for $p \notin E$, then $\pi(p^*, p) > \pi(p, p)$)) that is setwise asymptotically stable with respect to the replicator equation [6, 24]. Every symmetric game with two pure strategies is payoff equivalent to a game with a symmetric payoff matrix (i.e., these two games have the same NE and the same ESS etc.) and so has at least one ESSet. In fact, each two-strategy game has an ESS unless it is selectively neutral (i.e., unless $\pi(\hat{p}, p) = \pi(p, p)$ for all $p, \hat{p} \in \Delta^n$).

⁴For example, take $3.5 \leq \alpha < 14$ or $6.5 \leq \alpha < 14$ respectively in the RPS game of payoff matrix (5).

no other realization-equivalent strategies [12]. To ease this latter problem, Selten [31] defined an ESS directly in terms of behavior strategies (i.e., strategies that specify the local behavior at each player information set of the game tree). His *direct ESS* is then a behavior strategy b^* that satisfies conditions, (1) and (2) for any other behavior strategy b . Each direct ESS corresponds to a set of normal-form strategies that is an ESSet but the converse is not true [32]. In particular, b^* must still be pervasive and so a pure-strategy nonpervasive NE outcome that yields the strictly highest possible payoff whenever either player uses this strategy (e.g., an outside option) cannot be a direct ESS. Furthermore, every direct ESS can be found by applying the backward induction technique with respect to the ES structure of the subgames and their corresponding truncations [31] and so is a subgame-perfect NE. However, this technique often fails to yield a direct ESS [12] as Selten originally hoped.⁵

As an elementary example, consider backward induction applied to the symmetric extensive form game of Fig. 1 taken from Ref. 12. Its second-stage subgame $\begin{matrix} \ell & \begin{bmatrix} -5 & 5 \\ -4 & 4 \end{bmatrix} \\ r & \end{matrix}$ has mixed ESS $b_2^* = (\frac{1}{2}, \frac{1}{2})$ and when the second decision point of player one u_2 is replaced by the payoff 0 from b_2^* , the truncated single-stage game $\begin{matrix} L & \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \\ R & \end{matrix}$ also has a mixed ESS $b_1^* = (\frac{1}{2}, \frac{1}{2})$. Since both stage games have a mixed ESS (and so a unique NE since they are strictly stable), (b_1^*, b_2^*) is the only (behavior strategy) NE of Fig. 1 and it is pervasive. Surprisingly, this example has no direct ESS since (b_1^*, b_2^*) does not satisfy conditions (1) and (2) for the pure strategy b given by Rr [12].

Figure 1 shows that, although backward induction determines candidates for the ES structure, it is not useful for determining

Figure 1. The extensive form of the van Damme example.

which candidates are actually direct ESSs.⁶ However, applying backward induction with respect to NE that exhibit evolutionary stability in the subgames and in their truncations shows more promise. For instance, each direct ESS b^* yields an ESSet in the game's normal form [10] and so is dynamically stable. More interestingly, for the class of (symmetric) simultaneity games where both players know all player actions at earlier stages and there are no moves by nature, Cressman [10] shows that, if b^* is a pervasive NE, then the set of realization-equivalent normal-form strategies exhibits evolutionary stability with respect to the replicator equation if and only if it comes from this backward induction process. In

⁵Similar problems arise for his related limit ESS concept [12,33] and for the ESS concept defined in terms of reduced normal forms of the extensive form game (e.g., the reduced-strategy normal form of Cressman [10]).

⁶The situation is more discouraging for nonpervasive NE. For example, the only NE outcome of the two-stage repeated Prisoner's Dilemma Game [34] with cumulative payoffs is mutual defection at each stage. This nonpervasive NE outcome cannot be an isolated behavior strategy (i.e., there is a corresponding NE component) and so there is no direct ESS. Worse, for typical single-stage payoffs such as $\begin{matrix} \text{defect} & \begin{bmatrix} -1 & 10 \\ -2 & 5 \end{bmatrix} \\ \text{cooperate} & \end{matrix}$, this component does not satisfy setwise extensions of the ESS (e.g., it is not an ESSet). It does, however, attract all trajectories of the replicator equation for the standard normal form (or reduced-strategy normal form) for which all pure strategies initially have positive frequency.

particular, there is evolutionary stability for the NE of Fig. 1 (that corresponds to the unique NE of its reduced-strategy normal form).

So far, we have summarized evolutionary stability with respect to the replicator equation that was originally developed through the biological translation of fitness into reproductive success. The replicator equation also emerges through imitation based on rational decision processes such as the proportional imitation rule [35] whereby each player samples a random individual's strategy and payoff, switching to this strategy (i.e., imitating) when it has a higher payoff at a rate proportional to the expected gain. Other imitation rules lead to different evolutionary game dynamics that satisfy various monotonicity properties [13,36,37] between higher payoff and an increase in (relative) strategy frequency. In general, there is a complex relationship between evolutionary stability under these dynamics and heuristic static stability conditions such as those defining an ESS [9,11].⁷

More is known for the best response dynamics, whose discrete-time version (called *fictitious play*) predates the replicator equation [38]. The replicator equation and best response dynamics, based on different assumptions of player information, are considered to be the two standard game dynamics. For the best response dynamics [39], each player knows the current payoff of all strategies and, in particular, the best reply to the current population state $p \in \Delta^n$ given by the set

$$BR(p) \equiv \{p' \in \Delta^n : \pi(p', p) \geq \pi(p'', p) \text{ for all } p'' \in \Delta^n\}.$$

If a small proportion of the population switches per unit time to the current best

reply, we have the best response dynamics

$$\dot{p} \in BR(p) - p, \quad (6)$$

a differential inclusion for which solutions exist [11].⁸ These solutions are piecewise linear trajectories that enjoy many of the same evolutionary stability properties as the replicator equation. In particular, each ESS exhibits evolutionary stability under this dynamics [40] and for strictly stable games, the unique ESS is globally asymptotically stable.

Nonlinear Payoff Functions

For symmetric normal-form games, the payoff $\pi_i(\hat{p})$ of pure strategy e_i is linear in the components of the population state $\hat{p}$ (i.e., $\pi_i(\hat{p}) = \sum_{j=1}^n \pi(e_i, e_j) \hat{p}_j$). Symmetric games with payoff $\pi_i(\hat{p})$ nonlinear in the population state $\hat{p}$ are quite common in biology and in economics [9,22] where they are called *playing-the-field models* or *population games* since payoffs are not assumed to result from two-player pairwise interactions. Following the approach for two-strategy games outlined in the introductory section using $\pi(p, \hat{p}) = \sum_i p_i \pi_i(\hat{p})$, evolutionary stability of p^* can be characterized by local versions of conditions (1) and (2) (i.e., p is assumed to be close to p^* in these inequalities). A more common equivalent characterization, called local or neighborhood superiority [13,41], is that

$$\pi(p^*, p) > \pi(p, p), \quad (7)$$

for all p sufficiently close (but not equal) to p^* . In fact, for multistrategy symmetric normal-form games, linearity implies condition (7) is equivalent to the ESS of Definition 1 [15].⁹

⁷Two-strategy symmetric games are the exception. For these, any reasonable evolutionary game dynamics (i.e., one that increases the frequency of the better strategy) will have evolutionary stability at p^* if and only if p^* is an ESS.

⁸Solutions are Lipschitz continuous functions of t whose derivative satisfies Equation (6) almost everywhere. There may be more than one solution for the same initial conditions since the vector field $BR(p) - p$ is discontinuous and can be multiple valued.

⁹In fact, a p^* satisfying inequality (7) is often called an ESS. The exact definition of "ESS" in games that are not of symmetric normal form is not universally

In biology, an example of evolutionary stability reasoning before the advent of (evolutionary) game theory is Fisher's [44] justification for the prevalence of the 50:50 sex ratio in diploid species (see also the "unbeatable strategy" concept of Hamilton [45] that predicts other sex ratios under different reproductive scenarios). Specifically, individuals who produce equal numbers of male and female offspring have higher fitness than average in a population with a biased sex ratio (see the sex-ratio game in Ref. 22 where nonlinear fitness is given by the expected number of grandchildren).

In general, nonlinearity complicates the application of evolutionary stability theory. In fact, Vickers and Cannings [46] give an example where a discrepancy between two ESS definitions already arises for a symmetric normal-form game with a countably infinite set of pure strategies S . Similar problems occur in the definition of an ESSet [47,48] for nonlinear payoff functions. However, these issues do not seem to emerge in practical applications and it is the local superiority condition that is typically used to prove its evolutionary stability under the replicator equation (and its mixed strategy counterpart).

A more pressing problem is that it is often quite difficult to determine the locally superior strategies in these games. Even two-strategy games can have several ESSs in the interior of Δ^2 . To illustrate these issues, consider the class of potential games [9]. These are games for which there is a continuously differentiable real-valued function V (called the *potential function*) defined on a neighborhood of Δ^n whose gradient satisfies $\nabla V(\hat{p}) = (\pi_1(\hat{p}), \dots, \pi_n(\hat{p}))$ for all $\hat{p} \in \Delta^n$. (The doubly symmetric normal-form games are of this type with potential function $V(\hat{p}) \equiv \frac{1}{2}\pi(\hat{p}, \hat{p})$.) If V is a strictly concave function, then the game is strictly stable and the absolute maximum point of V is the unique locally superior strategy. For general V , the isolated local maxima of V correspond to local

superiority. However, finding the local maxima of the potential function is a nontrivial task, especially when the potential function is nonquadratic or perhaps unknown. For non-potential games, local superiority becomes still more complicated.

ASYMMETRIC GAMES

Evolutionary theory also applies to nonsymmetric games. Following Ref. 49 (see also Refs 10 and 12), in a two-player asymmetric game, the players interact in pairwise contests after they are assigned a pair of roles from a finite set of N roles with probability that is independent of player designation. Furthermore, a player in a given role has a finite set of possible pure strategies and payoffs to mixed strategists are given by a bilinear payoff function. An asymmetric game with $N = 1$ is then a symmetric normal-form game. This section summarizes evolutionary stability when $N = 2$ with (pure) strategy sets $S = \{e_1, \dots, e_n\}$ and $T = \{f_1, \dots, f_m\}$ for roles one and two respectively.

The invasion dynamics of the resident monomorphic population $(p^*, q^*) \in \Delta^n \times \Delta^m$ by (p, q) generalizes Equation (3) to become

$$\begin{aligned} \dot{\varepsilon}_1 &= \varepsilon_1(1 - \varepsilon_1) \\ &\quad \times \begin{bmatrix} \pi_1(p; \varepsilon_1 p + (1 - \varepsilon_1)p^*, \varepsilon_2 q + (1 - \varepsilon_2)q^*) \\ -\pi_1(p^*; \varepsilon_1 p + (1 - \varepsilon_1)p^*, \varepsilon_2 q + (1 - \varepsilon_2)q^*) \end{bmatrix} \\ \dot{\varepsilon}_2 &= \varepsilon_2(1 - \varepsilon_2) \\ &\quad \times \begin{bmatrix} \pi_2(q; \varepsilon_1 p + (1 - \varepsilon_1)p^*, \varepsilon_2 q + (1 - \varepsilon_2)q^*) \\ -\pi_2(q^*; \varepsilon_1 p + (1 - \varepsilon_1)p^*, \varepsilon_2 q + (1 - \varepsilon_2)q^*) \end{bmatrix}, \end{aligned} \quad (8)$$

where $\pi_1(p; \varepsilon_1 p + (1 - \varepsilon_1)p^*, \varepsilon_2 q + (1 - \varepsilon_2)q^*)$ is the payoff to p when the current state of the population in roles one and two are $\varepsilon_1 p + (1 - \varepsilon_1)p^*$ and $\varepsilon_2 q + (1 - \varepsilon_2)q^*$, respectively. From the biological perspective, this is a two-species system where an individual's fitness depends on both interspecific and intraspecific interactions. By Cressman [6], (p^*, q^*) exhibits evolutionary stability under Equation (8) (i.e., $(0, 0)$ is always asymptotically stable under the above dynamics for all

agreed upon. There are many concepts that use different terminology but have ESS-like features in these games [42,43].

choices $p \neq p^*$ and $q \neq q^*$) if and only if

$$\begin{aligned} \text{either} \quad & \pi_1(p; p, q) < \pi_1(p^*; p, q) \\ \text{or} \quad & \pi_2(q; p, q) < \pi_2(q^*; p, q). \end{aligned} \quad (9)$$

Condition (9) is the two role analogue of neighborhood superiority (Eq. 7).

If condition (9) holds for all $(p, q) \in \Delta^n \times \Delta^m$ sufficiently close (but not equal) to (p^*, q^*) , then (p^*, q^*) is called a *two-species* ESS [10] or neighborhood superior [50]. This ESS enjoys similar evolutionary stability properties to the ESS of symmetric games. It is asymptotically for the replicator equation

$$\begin{aligned} \dot{p}_i &= p_i [\pi_1(e_i; p, q) - \pi_1(p; p, q)], \\ \dot{q}_j &= q_j [\pi_2(f_j; p, q) - \pi_2(q; p, q)], \end{aligned} \quad (10)$$

and for all its mixed strategy counterparts (i.e., (p^*, q^*) is strongly stable). Furthermore, if (p^*, q^*) is in the interior of $\Delta^n \times \Delta^m$, then it is globally asymptotically stable [10]. It is also globally asymptotically stable under the best response dynamics that generalizes Equation (6) to asymmetric games.

The dynamics (Eq. 10) is called the *two-species replicator equation* when players in role i are identified with species i . A biological example of two-species evolutionary stability analysis is the two-habitat selection model of Cressman *et al.* [51] when there is a Lotka–Volterra competitive two-species system in each patch and migration is always toward the patch with the highest species' payoff. An ESS always exists in this model and, depending on parameters, the ESS is mixed (i.e., both species coexist in each patch) in some cases while, in others, one of the species resides only in one patch at the ESS.

Bimatrix Games

A particularly important class of asymmetric games is the set of N -role truly asymmetric games where the two players are never assigned the same role (i.e., players in the same role do not interact or, in biological terms, there are no intraspecific interactions). Then, the N -tuple giving a strategy in each role is an ESS if and only if it is a

strict NE [49], and if and only if it has evolutionary stability with respect to the replicator equation (10) [10].

Thus, in contrast to symmetric games, we have an equivalence between the static ESS concept (Eq. 9) and evolutionary stability. However, this is an unsatisfactory result in the sense that a strict NE must be a pure-strategy pair and so is a very restrictive concept. In particular, a mixed ESS as in the habitat selection model referred to above is impossible in a truly asymmetric game. We again illustrate these issues when $N = 2$.

Since $\pi_1(e_i; p, q)$ does not depend on p , we can use the notation $\pi_1(e_i, q)$ instead (and also replace $\pi_2(f_j; p, q)$ with $\pi_2(p, f_j)$). Such a game is then represented by an $n \times m$ bimatrix (A, B) whose ij th entry is the pair of payoffs $(\pi_1(e_i, f_j), \pi_2(e_i, f_j))$ to the players in the two roles for the interspecific interaction between e_i and f_j . Standard examples, with two strategies for each player, include the Buyer–Seller Game [10] that has no ESS since its only NE is in the interior. Another is the Owner–Intruder Game (the bimatrix version of the Hawk–Dove Game) that has two strict NE which Maynard Smith [22] called the *bourgeois* ESS where the owners defend their territory (i.e., play Hawk if and only if the owner) and the paradoxical ESS where owners retreat (i.e., play Hawk if and only if the intruder).

One attempt to relax the ESS conditions in bimatrix games is through the concept of a strict equilibrium set (SESet), the analogue of the ESSet. This is a set F of NE (p^*, q^*) such that $(p, q^*) \in F$ if $\pi_1(p, q^*) = \pi_1(p^*, q^*)$ and $(p^*, q) \in F$ if $\pi_2(p^*, q) = \pi_2(p^*, q^*)$. Such sets correspond to the asymptotically stable sets of rest points of the replicator equation [10,11,52]. However, an SESet is still quite restrictive since F must contain all strategies p with support equal to or contained in any p^* with $(p^*, q^*) \in F$ and so cannot contain an interior NE (unless every strategy pair is Nash).

On the other hand, the Nash–Pareto pair of Hofbauer and Sigmund [4] does allow for isolated mixed strategy solutions. (p^*, q^*) is a Nash–Pareto pair if any pair of best replies (p, q) satisfies

$$\begin{aligned} &\text{either } \pi_1(p, q) \leq \pi_1(p^*, q) \\ &\quad \text{or } \pi_2(p, q) < \pi_2(p, q^*) \end{aligned}$$

and

$$\begin{aligned} &\text{either } \pi_2(p, q) \leq \pi_2(p, q^*) \\ &\quad \text{or } \pi_1(p, q) < \pi_1(p^*, q). \end{aligned}$$

Notice that both these inequality conditions are similar to condition (9). An example of a Nash–Pareto pair is the only NE of the Buyer–Seller Game. A noteworthy connection to evolutionary stability is that every Nash–Pareto pair is neutrally stable with respect to the replicator equation (10) [4].

CONCLUSION

The static ESS fitness comparisons introduced by Maynard Smith to predict the behavioral outcome of evolution in a single species have been extended in many directions during the intervening thirty years. These include biological extensions to multiple species and to population games as well as the equally important extensions to predict rational individual behavior in human conflict situations. As is apparent from this article, there is a complex relationship between these static conditions and evolutionary stability of the underlying dynamical system. Interestingly, the stability analysis has in many cases been determined before its connection with the ESS perspective was recognized.

This article has summarized evolutionary stability for deterministic evolutionary game dynamics based on random pairwise interactions in (symmetric or asymmetric) normal-form games. Evolutionary stability is also of much current interest for other game-theoretic models such as those that incorporate stochastic effects due to finite populations [20]; models of adaptive dynamics based on continuous (pure) strategy spaces [21,53,54]; models with assortative (i.e., nonrandom) interactions (e.g., games on graphs) [20]. There is also a great deal of interest, both theoretically and experimentally, on models for the evolution of human

cooperation whose underlying games are either the two-player Prisoner’s Dilemma Game or the multiplayer Public Goods Game [55]. As the evolutionary theory behind these models is a rapidly expanding area of current research, it is impossible to know in what guise evolutionary stability conditions will emerge in future applications. On the other hand, it is certain that Maynard Smith’s original idea will continue to play a central role.

EXACT SOLUTION OF THE CAPACITATED VEHICLE ROUTING PROBLEM

ROBERTO BALDACCI
DANIELE VIGO
DEIS, University of Bologna,
Cesena, Italy
PAOLO TOTH
DEIS, University of Bologna,
Bologna, Italy

INTRODUCTION

Vehicle routing problem (VRP) is a generic name given to a whole class of problems concerning the optimal design of routes to be used by a fleet of vehicles to serve a set of customers. Since it was first proposed by Dantzig and Ramser [1], hundreds of papers have been devoted to the exact and approximate solution of a member of the VRP class, known as the *capacitated vehicle routing problem* (CVRP), in which a homogeneous fleet of vehicles is available at a central depot, each vehicle can take a single route, and the only constraint considered is the vehicle capacity constraint.

An interesting survey covering the early exact methods for the CVRP is presented by Laporte and Nobert [2], and the book edited by Toth and Vigo [3] provides a comprehensive overview of exact methods for the CVRP and other variants proposed up to the end of the twentieth century. This work was updated from the survey of Cordeau *et al.* [4]. Recent surveys can be found in Baldacci *et al.* [5] and Bladacci *et al.* [6]. Many different heuristic algorithms are proposed in the literature for the CVRP and its variants. Among the various surveys on heuristic algorithms for the CVRP, we mention the surveys of Laporte and Semet [7] and of Gendreau *et al.* [8] in the book edited by Toth and Vigo [3].

In this article, we provide a review of the developments in the exact solution of the

CVRP on undirected graphs that had a major impact in the current state-of-the-art exact algorithms for this problem family. In particular, we present two mathematical formulations proposed in the literature that were used in the most successful exact approaches. We briefly survey the best-known exact algorithms that can be classified into the following categories: branch-and-bound, dynamic programming (DP), branch-and-cut, branch-and-cut-and-price, and set partitioning-based methods. As previously mentioned, we concentrate here on the undirected version of the problem since this is the most widely studied.

This article is organized as follows: In the following section we formally describe the CVRP and introduce the notation that will be used throughout the paper. The section titled “Mathematical Formulations of the CVRP” reviews two formulations and briefly describes the valid inequalities proposed for them. The section titled “Exact Methods for the CVRP” reviews the exact algorithms, while a comparison of the computational performances of the recent exact methods is reported in the final section.

PROBLEM DEFINITION AND BASIC NOTATION

In this section, we give a formal definition of the CVRP and introduce the relevant notation required to define the mathematical formulations.

In the CVRP all the customers correspond to deliveries, the demands are deterministic, known in advance, and may not be split. The vehicles are identical and based at a single central depot, each taking up exactly one route, and only the capacity restrictions for the vehicles are imposed. The objective is to minimize the total cost (i.e., their length or travel time) to serve all the customers.

More precisely, the CVRP may be described as the following graph theoretic problem.

Let $G = (V, E)$ be a complete and undirected graph where $V = \{0, \dots, n\}$ is the vertex set and E is the edge set. Vertex set $V_c = \{1, \dots, n\}$ corresponds to n customers, whereas vertex 0 corresponds to the depot. A nonnegative cost, d_{ij} , is associated with each edge $\{i, j\} \in E$ and represents the travel cost spent to go directly from vertex i to vertex j . In several practical cases, the cost matrix $D = [d_{ij}]$ satisfies the *triangle inequality*. Each customer $i \in V_c$ is associated with a known nonnegative demand, q_i , to be delivered. A set of m identical vehicles, each with capacity Q , is available at the depot. We assume that $q_i \leq Q$ for each $i \in V_c$. A *feasible route* (or simply *route*) is a simple cycle in G passing through the depot and a subset of customers of V_c such that the sum of the customer demands is less than or equal to Q .

In the variant of CVRP that is generally considered in the literature and that we study here, all available vehicles must be used, each performing exactly one route. We also assume that m is not smaller than $m_{\min}$, which is the minimum number of vehicles needed to serve all the customers. The value of $m_{\min}$ may be determined by solving the bin packing problem (BPP) associated with the CVRP, which calls for the determination of the minimum number of bins (i.e., vehicles), each with capacity Q , required to load all the n items (i.e., customers), each with nonnegative weight q_i , $i \in V_c$.

The CVRP consists of finding a collection of exactly m routes with minimum cost, defined as the sum of the costs of the edges belonging to the routes, and such that each customer vertex is visited by exactly one route.

The CVRP is known to be $\mathcal{NP}$ -hard (in the strong sense), and generalizes the well-known traveling salesman problem (TSP), which calls for the determination of a minimum cost simple cycle visiting all the vertices of G (Hamiltonian cycle), and arising when $Q \geq \sum_{i \in V_c} q_i$ and $m = 1$.

If G is a directed graph and the cost matrix D is asymmetric, the corresponding problem is called *asymmetric capacitated vehicle routing problem* (henceforth indicated as ACVRP).

An important variant of the basic CVRP, which received great attention in the scientific literature, arises when the vehicle fleet is characterized by different capacities and costs. This problem is generally known as *heterogeneous VRP*. A specific survey on heterogeneous VRPs can be found in Baldacci *et al.* [9].

MATHEMATICAL FORMULATIONS OF THE CVRP

In this section, we describe two mathematical formulations of the CVRP that were used in the most successful exact algorithms, namely, the *two-index vehicle flow* and *set partitioning* formulations.

In addition to the notation already introduced, for a subset $S \subseteq V_c$, let $\delta(S)$ be the *cutset* defined by S (i.e., $\delta(S) = \{\{i, j\} \in E : i \in S, j \notin S \text{ or } i \notin S, j \in S\}$). Moreover, we denote by $q(S)$ the total demand of the customers in S and by $\mathcal{S}$ the set $\{S : S \subseteq V_c, |S| \geq 2\}$.

Two-Index Vehicle Flow Formulation

The so-called vehicle flow formulations use binary decision variables to indicate if a vehicle travels between a pair of vertices in G . In *three-index* models there is a specific variable for each vehicle and vertex pair, whereas *two-index* models aggregate this information over the different vehicles.

The *two-index vehicle flow* formulation of the CVRP was originally proposed by Laporte *et al.* [10] and is as follows: Let x_{ij} be an integer variable which may take value in $\{0, 1\}$, $\forall \{i, j\} \in E \setminus \{\{0, j\} : j \in V_c\}$ and value in $\{0, 1, 2\}$, $\forall \{0, j\}$, $j \in V_c$, with $x_{ij} = 1$ when edge $\{i, j\}$ is traveled, and $x_{0j} = 2$ when a route including the single customer j is selected in the solution. Then, the CVRP can be formulated as the following integer linear program (LP):

$$\min \sum_{\{i, j\} \in E} d_{ij} x_{ij} \quad (1)$$

$$\text{s.t.} \quad \sum_{\{i, j\} \in \delta(\{h\})} x_{ij} = 2, \quad h \in V_c, \quad (2)$$

$$\sum_{\{i, j\} \in \delta(S)} x_{ij} \geq 2 \lceil q(S)/Q \rceil, \quad S \in \mathcal{S}, \quad (3)$$

$$\sum_{j \in V_c} x_{0j} = 2m, \quad (4)$$

$$x_{ij} \in \{0, 1\}, \quad \{i, j\} \in E \setminus \{\{0, j\} : j \in V_c\}, \quad (5)$$

$$x_{0j} \in \{0, 1, 2\}, \quad \{0, j\}, j \in V_c. \quad (6)$$

Constraints (2) are the degree constraints for each customer. Constraints (3) are the so-called *Rounded Capacity* (RC) inequality which, for any subset S of customers that does not include the depot, imposes the condition that at least $\lceil q(S)/Q \rceil$ vehicles enter and leave it. These constraints impose both, the capacity and the connectivity constraints. Constraint (4) states that m vehicles must leave and return to the depot, while constraints (5) and (6) are the integrality constraints.

Golden *et al.* [11] formulated the CVRP using three-index binary variables x_{ij}^k as vehicle flow variables to indicate whether vehicle k travels directly from customer i to customer j ($x_{ij}^k = 1$ if vehicle k travels directly from customer i to customer j , 0 otherwise). This formulation is generally used when additional route constraints, such as heterogeneous vehicle fleet and working time constraints, must be imposed.

The two- and three-index vehicle flow models have an exponential number of constraints to enforce connectivity. Several alternative models impose this requirement by using a set of continuous variables representing the flow of one or more “commodities” between the depot and the customers. These formulations were presented by Gavish and Graves [12], and subsequently explored by Gouveia [13] and Baldacci *et al.* [14].

Set Partitioning Formulation

The set partitioning formulation of the CVRP was originally proposed by Balinski and Quandt [15] and associates a binary variable with each *feasible* route.

Let $\mathcal{R}$ be the index set of all feasible routes and let $a_{i\ell}$ be a binary coefficient that is equal to 1 if vertex $i \in V$ belongs to route $\ell \in \mathcal{R}$ and takes the value 0 otherwise (note that $a_{0\ell} = 1, \forall \ell \in \mathcal{R}$). In the following we will use $R_\ell = \{0, i_1, i_2, \dots, i_{h_\ell}\}$ to indicate the subset of

vertices visited by route $\ell \in \mathcal{R}$. Such a route represents the trip of one vehicle leaving the depot, serving the demands of the customers in $R_\ell \setminus \{0\}$, and returning to the depot. Each route $\ell \in \mathcal{R}$ has an associated cost c_ℓ , that is equal to the optimal solution cost of the TSP instance defined by R_ℓ .

Let ξ_ℓ be a binary variable that is equal to 1 if and only if route $\ell \in \mathcal{R}$ belongs to the optimal solution. The set partitioning formulation for the CVRP is as follows:

$$\min \sum_{\ell \in \mathcal{R}} c_\ell \xi_\ell \quad (7)$$

$$\text{s.t.} \quad \sum_{\ell \in \mathcal{R}} a_{i\ell} \xi_\ell = 1, \quad i \in V_c, \quad (8)$$

$$\sum_{\ell \in \mathcal{R}} \xi_\ell = m, \quad (9)$$

$$\xi_\ell \in \{0, 1\}, \quad \ell \in \mathcal{R}. \quad (10)$$

Constraints (8) specify that each customer $i \in V_c$ must be covered by one route and constraint (9) requires that m routes are selected.

This model is valid for any type of cost matrix D . However, if the cost matrix satisfies the triangle inequality, then equality constraint (8) can be written as a ‘ $\geq$ ’ inequality, thus obtaining the so-called *set covering* formulation that preserves the optimal objective function value [16]. The set partitioning formulation is very general and can take into account several route constraints (e.g., time windows, precedences, route lengths) since route feasibility is implicitly considered in the definition of set $\mathcal{R}$.

The set partitioning formulation described above remains valid if the set of routes $\mathcal{R}$ is enlarged with the set $\hat{\mathcal{R}} \supset \mathcal{R}$ containing, in addition to elementary routes, *nonelementary* routes, which are routes in which the vehicle is permitted to visit customers more than once. In this case, coefficient $a_{i\ell}$ is a general integer coefficient that is equal to the number of times customer i is visited by route ℓ . Note that the overall integer programming formulation remains valid, since constraints (8) ensures that the variables representing nonelementary routes will be automatically eliminated when ξ is binary.

Relaxations and Valid Inequalities

Valid lower bounds on the CVRP can be derived from the LP-relaxations of the mathematical formulations described in the previous section. Some of the resulting LPs cannot be solved directly, even for moderate size instances, since either the number of variables or constraints is exponential in the problem size. Thus, the lower bounds are usually computed using cutting-plane and column generation techniques. In addition, to strengthen the relaxations, a variety of valid inequalities have been described in the literature for the different formulations.

Valid inequalities for the vehicle flow formulations have been described by Laporte and Nobert [17], Cornuéjols and Harche [18], Fischetti *et al.* [19], Augerat *et al.* [20], and Letchford *et al.* [21] and a description of some of them for the two-index formulation can be found in Naddef and Rinaldi [22]. Conditions under which some of these inequalities induce facets of the CVRP polytope are discussed in Cornuéjols and Harche [18].

Valid inequalities for the two-index formulation, similar to the RC inequalities, can be obtained according to the way in which the right-hand side of constraints (3) is computed. For example, the *fractional capacity* (FC) inequalities take the form

$$\sum_{\{i,j\} \in \delta(S)} x_{ij} \geq 2 \frac{q(S)}{Q}, \quad S \in \mathcal{S}. \quad (11)$$

Note that, as $q(S)$ can be smaller than Q , the following *subtour elimination* (SE) inequalities are not dominated by the FC inequalities:

$$\sum_{\{i,j\} \in \delta(S)} x_{ij} \geq 2, \quad S \in \mathcal{S}. \quad (12)$$

Obviously, the RC inequalities dominate the FC and SE inequalities. However, the separation problem for RC inequalities was shown to be strongly $\mathcal{NP}$ -hard [22], whereas FC and SE inequalities can be easily separated in polynomial time.

More involved inequalities for the CVRP, such as *generalized capacity*, *framed capacity*, and *hypotour* inequalities were proposed by Augerat *et al.* [20]. Araque *et al.* [23]

defined the *multistar* and *partial multistar* inequalities for the CVRP with unit demands that were generalized by Letchford *et al.* [21] to the CVRP, yielding the so-called *homogeneous* multistar and partial multistar inequalities.

Other classes of valid inequalities have been presented for the polytope associated with the two-index formulation. In particular, some of these valid inequalities are based on the successful results of polyhedral combinatorics developed for the TSP by Chvátal [24] and by Grötschel and Padberg [25,26]. These include, among others, *comb* inequalities and *path-bin* inequalities [22].

Concerning the set partitioning formulation, results on which inequalities are implied by its LP-relaxation have been reported by Baldacci *et al.* [14], Letchford and Salazar González [27], and Baldacci *et al.* [28]. The latter authors have considered other valid inequalities designed for the general set partitioning problem, such as *clique* inequalities.

Systematic studies on how the different formulations proposed for the CVRP are related with each other can be found in Baldacci *et al.* [14] and Letchford and Salazar González [27].

EXACT METHODS FOR THE CVRP

The best-known exact algorithms for the CVRP are briefly surveyed below. These methods can be classified into the following categories: *branch-and-bound*, *dynamic programming*, *branch-and-cut*, *branch-and-cut-and-price*, and *set partitioning-based methods*.

Branch-and-Bound

The effectiveness of branch-and-bound algorithms largely depends on the quality of the lower bounds used to limit the search tree.

Christofides *et al.* [29] described a Lagrangean bound for the CVRP based on the set partitioning formulation where the columns correspond to the set of q -routes. A q -route is not necessarily a simple cycle covering the depot and a subset of customers whose total demand is equal to q . Some customers may be visited more than once,

and thus the set of feasible CVRP routes is strictly contained in the set of q -routes. The resulting branch-and-bound algorithm solved benchmark instances with up to 25 customers. Christofides *et al.* [29] also described a lower bound based on spanning trees, where the depot has degree k , with $m \leq k \leq 2m$.

Fisher [30] described a Lagrangean bound for the CVRP based on m -trees, which are spanning trees having degree $2m$ in the depot, and an exact branch-and-bound algorithm that has optimally solved a well-known problem with 100 customers. Finally, Miller [31] dualized vehicle capacity constraints in a Lagrangean fashion and worked on the resulting b -matching relaxation. The resulting branch-and-bound algorithm solved several benchmark instances containing up to 50 customers.

As to the ACVRP, Laporte *et al.* [32] proposed a branch-and-bound algorithm based on the use of the assignment problem (AP) relaxation that was able to solve randomly generated instances involving some tens of customers and two to four vehicles. Fischetti *et al.* [33] described two new lower bounds based on disjunction on infeasible arc subsets and on min-cost flow that improved on the AP relaxation. The new lower bounds were combined into an effective overall additive bounding procedure, according to the additive approach proposed by Fischetti and Toth [34] that allows for the combination of different lower bounding procedures, each exploiting different substructures of the considered problem. The resulting branch-and-bound approach was able to solve randomly generated instances with up to 300 vertices and 4 vehicles, and real-world instances with up to 70 vertices and 3 vehicles.

Dynamic Programming

DP has been applied to solve several variants of the CVRP or to obtain tight lower bounds.

Christofides *et al.* [35] presented three formulations of the CVRP and introduced the state-space relaxation method for relaxing the DP recursions in order to obtain valid lower bounds on the value of the optimal solutions. The computational results show

that the ratio “lower bound/optimum value” varies between 93.1% and 99.6% when these state-space relaxations are used. Christofides [36] reported that a CVRP instance involving 50 customers has been solved exactly by this approach. Instances involving up to 125 customers were solved within 2% of the optimum in less than 15 min on a CYBER 855 computer.

Branch-and-Cut

The first sophisticated branch-and-cut algorithm based on the two-index formulation for the CVRP was proposed by Augerat *et al.* [20]. The algorithm used a variety of valid inequalities that led to significant improvements in the quality of the lower bound. A detailed description of this work can be found in Naddef and Rinaldi [22].

Based on the original work of Augerat *et al.* [20], other branch-and-cut methods based on the two-index formulation have been recently proposed by Ralphs *et al.* [37] and Lysgaard *et al.* [38]. Ralphs *et al.* [37] described a branch-and-cut algorithm based on the two-index formulation and on the addition of the RC inequalities in a cutting-plane fashion. Lysgaard *et al.* [38] used a variety of valid inequalities, including the RC, framed capacity, strengthened comb, multistar, partial multistar, extended hypotour inequalities, and classical Gomory mixed-integer cuts.

Baldacci *et al.* [14] described a branch-and-cut algorithm based on a two-commodity formulation of the CVRP, where the RC inequalities were used in a cutting-plane fashion to strengthen the lower bound obtained by the LP-relaxation of the two-commodity formulation.

The most important aspect of any branch-and-cut algorithm is designing exact or heuristic algorithms that effectively separate a given fractional point from the convex hull of the integer solutions. Given a (fractional) point x^* , the separation problem associated with a given family $\mathcal{F}$ of valid inequalities consists of finding a member $\alpha x \geq \beta$ of $\mathcal{F}$, such that $\alpha x^* < \beta$. Several heuristic and exact algorithms have been designed for the separation problems associated with the different valid inequalities derived for the

CVRP. A detailed description of some of these algorithms can be found in Augerat *et al.* [20], Naddef and Rinaldi [22], Lysgaard *et al.* [38], and Augerat *et al.* [39].

Valid inequalities which play a crucial role in the development of a cutting-plane algorithm for the CVRP are the RC inequalities. Thus, a number of heuristic algorithms have been designed for their separation [20,38,39] and one of the most simple and effective techniques is the so-called *greedy randomized algorithm* proposed by Augerat *et al.* [20]. Fukasawa *et al.* [40] implemented exact separation procedures for the RC inequalities, based on mixed-integer models. They observed that the heuristic procedures typically decrease the separation times by two orders of magnitude without any significant loss in terms of bound quality. Ralphs *et al.* [37] described a decomposition-based separation methodology for the RC inequalities that takes advantage of the ability to solve small instances of the TSP efficiently.

Letchford *et al.* [21] described separation heuristic algorithms for the multistar and partial multistar inequalities, while separation algorithms for the other classes of inequalities including the comb, framed capacity, and hypotour inequalities, have been described by Augerat *et al.* [20] and Lysgaard *et al.* [38]. The complete set of the separation routines used by Lysgaard *et al.* [38] can be found in the software package CVRPSEP [41], which is publicly available.

Two branching strategies have been used by the different branch-and-cut algorithms for the CVRP proposed in the literature: the *branching on sets* strategy and the *branching on variables* strategy. The branching on sets strategy has been introduced by Augerat *et al.* [20]. This strategy consists of choosing a set S , $S \subseteq V_c$, $|S| > 2$, for which $0 < p(S) < 2$, where $p(S) = \sum_{\{i,j\} \in \delta(S)} x_{ij} - 2\lceil q(S)/Q \rceil$, and creating two subproblems: one by adding the constraint $\sum_{\{i,j\} \in \delta(S)} x_{ij} = 2\lceil q(S)/Q \rceil$ and the other by adding the constraint $\sum_{\{i,j\} \in \delta(S)} x_{ij} \geq 2\lceil q(S)/Q \rceil + 2$. The branching on variables strategy involves the selection of an edge $\{i,j\}$ having a fractional value of x_{ij} , and the generation of two subproblems: one by fixing $x_{ij} = 1$ and the other by fixing $x_{ij} = 0$.

The edge $\{i,j\}$ is selected in such a way that is as close as possible to 0.5 and ties are broken by choosing the edge $\{i,j\}$ having maximum cost d_{ij} .

Branch-and-Cut-and-Price

Fukasawa *et al.* [40] suggested an approach to combine both two-index and set partitioning formulations. In the formulation considered by Fukasawa *et al.* [40], the variables correspond to the set of q -routes [29], while the set of constraints is defined by the set partitioning formulation constraints plus feasible CVRP inequalities designed for the two-index formulation. In addition to the RC inequalities, they also used other valid inequalities, all presented in Lysgaard *et al.* [38]. The family $\mathcal{F}$ of the different valid inequalities designed for the two-index formulation can be expressed in a general form as

$$\sum_{\{i,j\} \in E} \alpha_{ij}^t x_{ij} \geq \beta^t, \quad t \in \mathcal{F}. \quad (13)$$

Since the resulting formulation has an exponential number of both columns and rows, column-and-cut generation procedures for computing the lower bound and a branch-and-cut-and-price algorithm for solving the CVRP were proposed. More precisely, Fukasawa *et al.* [40] considered the following relaxation of the CVRP:

$$\min \sum_{\ell \in \hat{\mathcal{R}}} c_\ell \xi_\ell \quad (14)$$

$$\text{s.t. } \sum_{\ell \in \hat{\mathcal{R}}} a_{i\ell} \xi_\ell = 1, \quad i \in V_c, \quad (15)$$

$$\sum_{\ell \in \hat{\mathcal{R}}} \xi_\ell = m, \quad (16)$$

$$\sum_{\ell \in \hat{\mathcal{R}}} \alpha^t(R_\ell) \xi_\ell \geq \beta^t, \quad t \in \mathcal{F}, \quad (17)$$

$$\xi_\ell \geq 0, \quad \ell \in \hat{\mathcal{R}}, \quad (18)$$

where $\alpha^t(R_\ell) = \sum_{\{i,j\} \in E} \alpha_{ij}^t \eta_{ij}^\ell$ and the set of routes $\hat{\mathcal{R}}$ corresponds to the set of q -routes. The coefficient η_{ij}^ℓ is a general integer coefficient that is equal to the number of times edge $\{i,j\}$ is traversed by q -route ℓ .

Fukasawa *et al.* [40] used a pricing and cut generation technique to solve the LP above. At first, the LP (i.e., *master problem*) includes only the degree constraints (15) and (16) and a restricted set of q -routes. The resulting lower bound has been integrated by Fukasawa *et al.* [40] in an enumeration scheme to solve the CVRP to optimality. The enumeration scheme is based on the branching on sets strategy described in the previous section.

The cut generation is performed by converting a solution ξ of the LP into a corresponding solution x . If this solution is fractional, it is given as input to the CVRPSEP package in order to separate the different classes of valid inequalities. The violated inequalities found are then translated back into the ξ variables to be introduced in the LP.

The pricing subproblem consists of finding q -routes with minimum reduced cost. Although this problem is $\mathcal{NP}$ -hard, it can be solved in pseudopolynomial time. Additional features of the branch-and-cut-and-price algorithm of Fukasawa *et al.* [40] are *cycle elimination*, *heuristic acceleration*, and *dynamic selection of column generation* (see Ref. 40 for details).

Based on the branch-and-cut-and-price algorithm described above, Pessoa *et al.* [42] proposed an exact method for the ACVRP.

Set Partitioning-Based Method

Balinski and Quandt [15] introduced the set partitioning formulation of the CVRP, where each column corresponds to a route. Agarwal *et al.* [43] proposed a column-generation algorithm on a modified set partitioning problem where column costs are given by a linear function over the customers, yielding a lower bound on the actual route cost.

Hadjiconstantinou *et al.* [44] described a method for computing a feasible dual solution of the LP-relaxation of the set partitioning formulation that is based on the computation of k -shortest paths and q -paths. The resulting CVRP lower bound is superior to the lower bound obtained by Christofides *et al.* [29] and the corresponding branch-and-bound algorithm was able to optimally solve benchmark instances involving up to 50 customers.

Mingozi *et al.* [45] presented a new method for solving the set partitioning formulation of the CVRP. They described a procedure for computing a valid lower bound that combines in an additive way different dual heuristics to find a near-optimal dual solution of the LP-relaxation of the set partitioning model. These dual heuristics are based on a bounding method proposed by Christofides *et al.* [29,35]. The dual solution obtained is then used to limit the set of the feasible routes containing the optimal CVRP solutions. The resulting set partitioning problem is solved by using a branch-and-bound algorithm. Mingozi *et al.* [45] report optimal solutions of benchmark instances with up to 50 customers.

Baldacci *et al.* [28] improved the method of Mingozi *et al.* [45] and derived a new exact method for the CVRP based on the following set partitioning model with additional cuts.

Let $H = (\mathcal{R}, \mathcal{E})$ be the *conflict graph* where each vertex corresponds to a route and the edge set $\mathcal{E}$ contains every pair $\{\ell, \ell'\}$, $\forall \ell, \ell' \in \mathcal{R}, \ell < \ell'$, such that $R_\ell \cap R_{\ell'} \neq \emptyset$. Let $\mathcal{C}$ be the set of all cliques of H . The integer model proposed by Baldacci *et al.* [28] is as follows:

$$\min \sum_{\ell \in \mathcal{R}} c_\ell \xi_\ell \quad (19)$$

$$\text{s.t.} \quad \sum_{\ell \in \mathcal{R}} a_{i\ell} \xi_\ell = 1, \quad i \in V_c, \quad (20)$$

$$\sum_{\ell \in \mathcal{R}} \xi_\ell = m, \quad (21)$$

$$\sum_{\ell \in \mathcal{R}(S)} \xi_\ell \geq \lceil q(S)/Q \rceil, \quad S \in \mathcal{S}, \quad (22)$$

$$\sum_{\ell \in \mathcal{R}} \alpha^t(R_\ell) \xi_\ell \geq \beta^t, \quad t \in \mathcal{T}, \quad (23)$$

$$\sum_{\ell \in C} \xi_\ell \leq 1, \quad C \in \mathcal{C}, \quad (24)$$

$$\xi_\ell \in \{0, 1\}, \quad \ell \in \mathcal{R}, \quad (25)$$

where $\mathcal{R}(S) = \{\ell \in \mathcal{R} : R_\ell \cap S \neq \emptyset\}$, $\alpha^t(R_\ell) = \sum_{(i,j) \in E} \alpha_{ij}^t \eta_{ij}^\ell$ and $\eta_{ij}^\ell = 1$ for each edge $\{i, j\}$ covered by route ℓ , 0 otherwise. Constraints (22) and (24) correspond to the *strengthened capacity constraints* and *clique inequalities*, respectively.

Baldacci *et al.* [28] proposed an additive bounding procedure that combines two dual ascent heuristics, called H^1 and H^2 , to derive a near-optimal dual solution that is used by a column-and-cut generation algorithm, called H^3 , to initialize the master problem. H^3 tries to close the integrality gap by adding in a cutting-plane fashion both strengthened capacity and clique constraints. The final dual solution achieved is then used to generate a reduced set partitioning problem containing only the routes whose reduced cost is smaller than the gap between an upper bound and the lower bound obtained. The resulting reduced problem is then solved through an integer linear programming solver.

The key components of this method are (i) the dual ascent scheme used by the bounding procedures H^1 and H^2 , (ii) the use of a state-space relaxation [35] to extend the route set with a relaxation of feasible routes that is easier to compute, and (iii) the use of bounding functions to reduce the state-space graph computed by DP when solving the pricing problem and generating the final set partitioning model.

Recently, Baldacci *et al.* [46] further improved the method given in an earlier study [28]. In particular, they used a new route relaxation, called *ng-route*, that improves other relaxations of feasible routes proposed in the literature for the CVRP and increases the efficiency of the pricing algorithms. They improved procedure H^3 using subset-row inequalities [47] and a novel strategy for solving the pricing subproblem. Finally, a new fathoming criterion based on the dual solution achieved by H^2 is used to speed up the solution of the pricing subproblems and reduce the size of the final set partitioning model.

The method described above provides a general solution framework that can be specialized to solve a number of VRP variants [48].

COMPUTATIONAL EXPERIMENTS FOR THE CVRP

Both analytical and computational results on the CVRP can be found in Baldacci *et al.*

[14], Augerat *et al.* [20], Letchford *et al.* [21], Naddef and Rinaldi [22], Baldacci *et al.* [28], Ralph *et al.* [37], Lysgaard *et al.* [38], Fukasawa *et al.* [40], and Baldacci *et al.* [46]. However, extensive computational results over a common set of instances taken from the literature have been performed only by the last four of these exact methods. Moreover, according to the results reported, the last four methods represent the most effective exact methods currently available for the CVRP, both for the quality of the lower bounds produced and for the number of instances solved to optimality. Thus, in this section, we report a comparison of the results obtained by the exact algorithms given in Baldacci *et al.* [28], Lysgaard *et al.* [38], Fukasawa *et al.* [40], and Baldacci *et al.* [46] on five classes of CVRP instances from the literature, called A, B, E, M, and P. These instances are available at <http://branchandcut.org/VRP/data>. Classes A, B, and P were proposed by Augerat [49]. Instance class M was proposed by Christofides *et al.* [50], and class E was produced by Christofides and Eilon [51].

The algorithm of Lysgaard *et al.* [38] was run on an Intel Celeron 700 MHz, whereas the algorithms of Baldacci *et al.* [28] and Fukasawa *et al.* [40] used Pentium 4 processors with 2.6 GHz and 2.4 GHz, respectively. The algorithm of Baldacci *et al.* [46] was run on an IBM Intel Xeon X7350 Server (2.93 GHz-16 GB of RAM). According to SPEC benchmarks (<http://www.spec.org/benchmarks.html>), the machine used by Baldacci *et al.* [46] is about three times faster than the Pentium 4 2.6 GHz PC used earlier by Baldacci *et al.* [28] and the Pentium 4 2.4 GHz PC of Fukasawa *et al.* [40], and ten times faster than the Intel Celeron 700 MHz PC of Lysgaard *et al.* [38].

Table 1 reports a summary of the computational results obtained by the exact methods given in Baldacci *et al.* [28], Lysgaard *et al.* [38], Fukasawa *et al.* [40], and Baldacci *et al.* [46]. Column *np* of this table reports the total number of instances in the corresponding class. For each method and for each class, the table reports the following data: number of instances solved to optimality (*nopt*), average percentage ratio of the lower bound with respect to the optimal solution value (%LB),

average time in seconds for computing the lower bound (*t*_{LB}) and average total time in seconds (*t*_{TOT}) both computed over all the instances solved to optimality. The last two lines of Table 1 report, for each method, the total number of instances solved to optimality and the averages of lower bounds and computing times computed over all instances solved to optimality by the method.

Table 2 reports a detailed comparison of the methods in Baldacci *et al.* [28], Lysgaard *et al.* [38], Fukasawa *et al.* [40], and Baldacci *et al.* [46] on difficult CVRP instances. Columns %LB, *t*_{LB}, and *t*_{TOT} of this table have the same meaning as in Table 1. Column *z** reports the cost of the optimal solution of each instance. For the exact method of Lysgaard *et al.* [38], “*tl*” indicates that the time limit has been reached, and

for the exact method of Baldacci *et al.* [28], “—” denotes that the memory limit has been reached.

The lower bounds reported in the tables for the methods of Lysgaard *et al.* [38] and Fukasawa *et al.* [40] are relative to the lower bounds computed at the root node of the corresponding decision trees, while the lower bounds of the methods of Baldacci *et al.* [28] and Baldacci *et al.* [46] are relative to the lower bound computed by bounding procedure H^3 .

The tables show that the method of Baldacci *et al.* [28] was not able to solve to optimality three instances solved by Fukasawa *et al.* [40] and by Baldacci *et al.* [46]. Table 1 indicates that the lower bounds of Baldacci *et al.* 28 and 46 are on average superior to the lower bounds of Lysgaard *et al.* [38] and Fukasawa *et al.* [40] in all classes of instances considered. Taking the different computers used into account, Table 1 indicates that the method of Baldacci *et al.* [46] outperforms the other methods.

FAIRNESS AND EQUITY IN SOCIETAL DECISION ANALYSIS

L. ROBIN KELLER

University of California Irvine,
Irvine, California

TIANJUN FENG

Fudan University, School of
Management, Shanghai, China

Imagine you divide three cookies between your two children, five-year-old Jack and two-year-old Jill. You might give Jack two cookies and Jill one cookie. But, then Jill will claim that this division is unfair, and will remain unconvinced even when you say that Jack is older and bigger and thus needs (and deserves) more food.

In such a parental role, you may decide to give equal cookie allocations in the future, ignoring arguably good reasons for giving an unequal allocation. Such an equal allocation is particularly appealing when the recipients all know what each person was given and have the opportunity to express their feelings about their allocation. But, sometimes, an unequal distribution will seem to be the most fair and equitable, given the special features of the situation. For example, whenever there is a single undividable item, such as a family heirloom, which needs to be somehow allocated, the resulting distribution will be unequal, but a fair process may be used to determine the allocation.

Just as it is important to consider fairness in making allocations within a family, fairness plays an important role in making societal decisions, such as where to locate hazardous facilities or how to apportion benefits and costs among different parties. In the operations research literature, fairness and equity are often used interchangeably, usually referring to perceptions of the appropriateness of allocations of risks, benefits, and costs (or of the allocation process). A variety of social science domains investigate

such allocations, and use a variety of terms to define specific types of fairness (such as *procedural* justice). The aim of this article is to focus primarily on how decision analysts and behavioral decision theorists (within the operations research community) have examined fairness, and provide some introduction and references to coverage in other disciplines. The section titled “Levels of Fairness Investigations” describes different levels of fairness investigations. The section titled “Fairness Factors and Issues to Consider in Societal Decision Models” presents fairness factors and issues to consider in constructing societal decision models. And the section titled “Decision Scenarios Involving Fairness and Experimental Results” presents some examples of decision scenarios involving fairness and experimental results for those scenarios.

LEVELS OF FAIRNESS INVESTIGATIONS

Fairness or equity can be examined from different perspectives. We present some of these below and provide some very brief examples of ways of looking at fairness at each of these levels.

To an Individual

Is it fair to pay a person less because he is single and has no family responsibilities? Is it fair to give priority to admitting a college student from a historically underrepresented racial or ethnic group? Is it fair to charge a customer more for an umbrella on the day it rains? Is it fair to pay a firefighter more than an office manager, since the firefighter faces more job safety risks?

Kahneman *et al.* [1,2] discuss different conditions under which an allocation of a cost or a benefit to an individual is seen as fair, and report results of a survey of the general (Canadian) public about scenarios such as fair pay and fair prices. In a laboratory experiment, Mellers [3] examines what fairness principles appear to be used by

experimental subjects in allocating salaries or taxes. When focusing on fairness to an individual, there still are usually implicit comparisons with what others in similar situations will receive or comparisons with the process that is used with others.

Within Families

How can heirs fairly decide which heir should get the sentimentally important stamp collection? During a divorce case, does the wife get a better deal than the husband, or is the settlement fair?

Pratt and Zeckhauser [4] describe how to fairly divide a number of silver heirlooms among heirs, where each heir's preferences for objects are represented by his or her utility function, then allocations to different heirs are made as they would be in a market for probability shares in the items, assuming each heir has an equal budget for making purchases and the item prices are the market-clearing equilibrium prices in a second-price auction.

In a married couple, each person brings some inputs to their marriage and receives benefits from the marriage, in some proportion to their inputs. The Walster *et al.* [5] book on equity theory addresses issues such as equity within a marriage (and in other settings).

Between Interested Entities/Parties

How fair is the \$2/h raise the university gave its lowest paid workers and the salary cut it gave other workers? How much of a movie's revenue should go to the actors versus the producers?

In cases involving disputes over revenue sharing between joint enterprise partners or negotiations in real estate transactions, involved parties (i.e., people, business, trade organizations, etc.) care about the fairness of the process and the eventual allocation. There is a large body of mathematical research dealing with this type of situation, which is called the *Cake-cutting problem* [6,7]. In this problem, "cake" could mean any desirable goods or benefits and "cutting" means the methods people use to divide them. The basic question—how to fairly cut

a cake—represents many issues involving multiple interested groups that want to share an entity fairly. Robertson and Webb [6] focus on three main issues in their mathematical survey of the cake-cutting problem: (i) the existence of a solution; (ii) the procedure to construct the solution; and (iii) what are the properties of the procedure to the solution. Brams and Taylor [7] address fair division from the cake-cutting problem to dispute resolution. Also see Raiffa's [8] book on negotiation methods and Camerer and Thaler [9] for related game theoretic experiments and results. Hoffman and Spitzer [10] examined participants' concepts of distributive justice in a laboratory experiment and Margolis' [11] book addresses how one person allocates outcomes to another in either a selfish or an altruistic way.

Within an Organization

Considering how much work I did on a project, did I get a fair amount of recognition for my contribution? How fair is the personnel process at my company? How fairly did my boss treat me during the last round of bonus allocations?

Organizational behavior researchers examine workplace fairness in terms of distributive justice, procedural justice, and interactional justice, and then examine the effects of perceived justice on behaviors, such as workplace revenge. Distributive justice refers to whether the outcome in a case is seen as fair, given the inputs [12,13]. Procedural justice focuses on the process by which outcomes are distributed [14]. Interactional justice is concerned primarily with how people are treated [15]. When observers within an organization see how others are treated they may want to believe that people get what they deserve and that there is a "just world" [16,17].

Comparing Within a Region or Nation

How fair is the distribution of land ownership or wealth in a country? How should we examine fairness of electric utility pricing within a region or nation? Do underprivileged groups face more environmental risks?

Rawls [18] discussed the theoretical notion of imagining oneself behind a veil of ignorance about which location in a society would ultimately be held by that person. Then, a person can consider what would be a fair distribution across the society, in ignorance of whether that person's ultimate fate would end up as being in a rich or a poor position. He then proposed that in the "original position" behind the veil a person would adopt a maximin strategy, which would maximize the position of the least well-off person (who has the minimum allocation). Economist John Harsanyi had a similar discussion in his work on the social welfare theory of utilitarianism. Suppes [19] also examined the distributive justice of income inequality. Zajac [20,21] examined fairness in public utility regulations. Zimmerman and colleagues [22–25] empirically examined the fairness of actual distributions of environmental risks, particularly to people in poorer areas, calling this field "environmental justice."

Comparing People Across Nations

How far apart are the wealthy and the poor in one country versus another? Do the same concepts of fairness apply in the United States and in China?

One can graph the distribution of family income within one country and compare it with the distribution in other countries. For a group of N families, the graph called a *Lorenz curve* plots the cumulative family income for the poorest x families on the y -axis against the number of families arranged on the x -axis from the poorest family (#1) to the richest family (# N). If all N families have the same income, which is presumably most fair, then the Lorenz curve is the straight 45° line. If many families have low incomes and only a few have high incomes, the Lorenz curve is convex and falls far below the straight 45° line. A popular way to make a comparison of the distribution in different countries is to use the Gini index, which is calculated from the Lorenz curve by computing the ratio of the area between a country's Lorenz curve and the 45° line divided by the entire triangular area under the 45° line. Therefore, a higher Gini index indicates more inequality. The scores

for different countries and an explanation of the calculation of the index are at <https://www.cia.gov/library/publications/the-world-factbook/fields/2172.html>.

There are differences in fairness perceptions between cultures. In some countries, the closest word to the English word fairness may be justice or balance. Interestingly, in the Canadian public survey [2], respondents answered on a bipolar scale, anchored by acceptable and unfair. For many in Western countries, these two concepts may indeed be two ends of a single scale. Certainly, when a child complains about unfairness in cookie allocations, it usually also means the allocation is unacceptable. However, from some other perspectives, such as those of Chinese, there may be two different dimensions: unfair to fair versus unacceptable to acceptable; see Bian and Keller [26, p. 317]. Bian and Keller found that Chinese [27] agreed with Americans [28] on fairness judgments involving societal risks, but disagreed on the best actions to take. In some cases, where there was a chance that a large group would die, the Americans would take the action that they saw as fair, but Chinese would not. In interviews with Chinese [27], it appeared that when the cultural value of treating everyone equally was in conflict with the value of preventing the extinction of the whole community, Chinese would take actions to avoid extinction of the community; see also Keller *et al.* [29] for additional details on these studies on "risk equity," which involved scenarios with probability distributions over health or safety outcomes.

FAIRNESS FACTORS AND ISSUES TO CONSIDER IN SOCIETAL DECISION MODELS

When I ask you if a particular allocation or transaction process is fair, you will likely respond, "it depends." Perceptions of fairness can depend on a variety of current and preexisting factors and issues. Fairness is also in the "eye of the beholder," so a person from one culture or one point of view may see unfairness when another person sees fairness. In the cookie example, Jack may see it as fair that he, the older child, gets two cookies, but Jill sees it as unfair.

While a parent may use an equal division of cookies among children, in many cases equal distribution is not feasible or prudent. A good introduction to different concepts of fair division is in Yaari and Bar-Hillel's [30] paper on dividing justly. They identified six categories of factors which "provide a possible justification for departure from equality," including the following:

1. differences in needs;
2. differences in tastes, or in the capacity to enjoy various goods;
3. differences in beliefs;
4. differences in endowments;
5. differences in effort, in productivity, or in contribution;
6. differences in rights or in legitimate claims.

When you are in charge of a societal decision analysis, which involves different outcomes (such as monetary benefits or costs, health and safety risks, etc.) to different people, you may want to ask yourself a number of questions to determine which factors should be considered in your decision process. Examples of such societal decisions are selecting a hazardous waste processing site in a region, choosing where to send emergency personnel in a major disaster, and budget allocation between elementary and middle schools. A few of the possible questions to ask before constructing your decision analysis model and process are listed below.

From the Perspective of an Outside Society Member, Does it Matter What the Different Parties Get?

Suppose an outsider does not receive any part of an allocation. Would that person care how the allocation is divided among those who receive an allocation? In such a case, the societal decision maker may wish to spread the allocation more fairly even if those affected do not know or do not care about what others get. See Lichtenstein *et al.* [31] and Wagenaar *et al.* [32] for discussions of the perspective of the societal decision maker and for some stylized societal decision scenarios. One thing that may matter to the

public or the decision maker is if the decision maker takes an action to give people unequal allocations or if the decision maker passively allows already occurring inequalities to remain.

Do the Different Affected Parties Care What Others Get?

Direct observation of others (such as watching children like Jack and Jill) or self-introspection will likely lead to the answer "yes." Yet, simple economic models often assume that a person merely cares about his own allocation. This makes it appear that economists tend not to be concerned about a person being selfish (since that is what such models would expect to occur) and tend to be baffled that a person would be altruistic. Indeed, they may work hard to explain altruistic behavior within the scope of such models by assuming that the altruism somehow helps the individual. For a different point of view, see the books by Margolis [11] on *Selfishness, Altruism, and Rationality* and Robert Frank [33] on *Choosing the Right Pond* for economic discussions in which people care about what others get.

Do the Different Parties Know What Others Get? Do They Know What Different Parties Started Out with or Did to "Deserve" Their Outcomes?

Often, fairness disputes may develop because affected parties do not know all the historical or preceding factors that may support an unequal allocation to one person in comparison with another. A raise may make up for not getting a raise in the last round of merit reviews, for example. See Mellers and Baron's edited book [34], *Psychological Perspectives on Justice*, for discussion of various components of fairness perception.

If the different parties care about what others get, and know what others get, then you may want your decision analysis model to keep track of allocation differences between neighbors or others who compare themselves, since such differences might be important. In some cases, you may choose to reveal the

allocation process and outcomes for all parties, even if the parties would not normally have been able to observe these.

Do the Different Parties Prefer that They Get the Same Outcome at the Same Time or, in Contrast, Do They Prefer That They Get the Outcome at Different Times?

The concept of common fate equity refers to situations where a set of people would like to experience the same “common” outcome simultaneously, even if it is a bad outcome. They prefer sharing a common fate over experiencing common fate inequity, where they would experience a bad (or good) outcome separately.

Parents of young children may choose to not fly together, so that they do not share the common fate of both dying together in the same airplane crash. Companies often have rules that top executives cannot fly together for a similar reason. In such cases, these rules avoid the parents or executives experiencing the common fate of dying from the same risky event. Sadly, such common fate events, though rare, do occur, such as the crash of the presidential plane carrying President Lech Kaczynski of Poland and 95 others including his wife, lawmakers, military commanders, priests, and others on April 10, 2010.

An axiom of preference for *common fate inequity* captures the preference to avoid common fates in decision analysis models. In other situations, a common fate will be preferred. See Fishburn’s [35] common fate equity axiom E4 and a newer treatment of a preference for “shared destinies” in Ref. 36. A decision scenario illustrating common fate preference among experiment participants [27,28] is in the section titled “Decision Scenarios Involving Fairness and Experimental Results” below.

Is It Possible for Parties to Trade Their Allocations to Achieve Better Outcomes?

Sometimes it is possible to adjust allocations among parties enough that they will see the final allocation as fair. One concept of fairness in this case is an *envy-free* allocation, one where no one envies what any other person has, and would not want to switch his own

allocation for another’s allocation. Keller and Sarin [28] present an envy-free risk-benefit model. However, there may be no envy-free allocation possible. In such cases, the societal decision maker must make difficult trade-offs, especially when health and safety risks are involved and there are shortages of life-saving resources (such as donated kidneys for kidney transplant surgeries). Calabresi and Bobbitt [37] identify four approaches in such “tragic choices”: pure market, accountable political, lottery (such as a military draft), and customary or evolutionary mechanisms.

Should Fairness to Future Generations be Considered?

When societal decisions may have effects on future generations, the fairness of the outcomes to those currently living compared to future generations may need to be considered. When called for, economists and decision analysts build considerations of intergenerational effects into their models. For example, Morton *et al.* [38] created a multiple objective decision analysis model to make recommendations to the UK government on what should be done with accumulating radioactive waste. One of their objectives was reducing “burden on future generations,” which was an influential objective when the decision of deep disposal of waste would be the preferred option over other storage options.

DECISION SCENARIOS INVOLVING FAIRNESS AND EXPERIMENTAL RESULTS

In this section, we give examples of decision scenarios involving allocations between people (of healthy foods or safety risks) and show what survey respondents chose.

Healthy Fruit Allocation Scenario

Yaari and Bar-Hillel [30] conducted an experimental survey to examine what choices participants would make in a number of scenarios where allocations across people would be made. They then examined the predominant choice pattern to see how it aligns with different concepts of fairness. Here is their first question, from Ref. 30:

A shipment containing 12 grapefruit and 12 avocados is to be distributed between Jones and Smith. The following information is given, and is also known to the two recipients:

- Doctors have determined that Jones's metabolism is such that his body derives 100 ml of vitamin F from each grapefruit consumed, while it derives no vitamin F whatsoever from avocado.
- Doctors have also determined that Smith's metabolism is such that his body derives 50 ml of vitamin F from each grapefruit consumed and also from each avocado consumed.
- Both persons, Jones and Smith, are interested in the consumption of grapefruit and/or avocados only insofar as such consumption provides vitamin F—and the more the better. All the other traits of the two fruits (such as taste, calorie content, etc.) are of no consequence to them.
- No trades can be made after the division takes place.

How should the fruits be divided between Jones and Smith if the division is to be just?

A large majority (82%) of Yaari and Bar-Hillel's 163 young adult respondents chose for Jones to have 8 grapefruits and 0 avocados (remembering that avocados did not benefit him at all) and for Smith to have 4 grapefruits and 12 avocados. Only 8% of the participants chose an equal division of six grapefruits and six avocados to each person. Therefore, in this case, the number of milligrammes of vitamin F [8×100 for Jones and $(4 \times 50) + (12 \times 50)$ for Smith] were equated on the basis of how much each person needed to eat to get the vitamin benefit, rather than the number of fruits.

Subsequent similar scenarios in Ref. 30 involve variations of needs, tastes, and beliefs. Proceeding through these examples, many subtle variations in fairness judgments are demonstrated. In societal decision analyses potentially involving similar subtle variations in fairness, it is important for decision models to keep track of such factors that would be important to the members of society for whom the decision is to be made.

Rescuer at Risk Scenario

Next, we consider the "Rescuer at Risk" scenario from an experimental survey conducted by Keller and Sarin [28] with American respondents and by Bian and Keller [27] with Chinese respondents:

On an island within your jurisdiction, 100 miners are trapped in one location in a mine. There is a way to rescue these miners by sending a rescue team through an unused tunnel. You have dispatched a rescue team of 10 rescuers to this tunnel. The team has come upon a portion of the tunnel that is dangerous. They need to station a rescuer at this point in the tunnel for the next 10 h to listen and watch for any signs that the trapped miners send to the team. However, there is a chance that, sometime in the next 10 h, a cave-in will occur, which will be fatal to the rescuer stationed there. The rest of the tunnel is safe, so the rescuers are not at a risk in other parts of the tunnel. The team is able to communicate with you at a command post via a portable radio. The team has contacted you for your orders about what to do next. They want to know if they should station one rescuer at the key point in the tunnel for 10 h or have each rescuer take a 1-h shift. There is a 10% chance that a cave-in will occur, and only one cave-in would occur, if any. The rescuers will definitely be able to save the 100 miners, no matter which option is taken.

Option 1.

One rescuer does the entire 10-h shift.
This rescuer has a 10% chance of death.
The other nine rescuers have a 0% chance of death.

Option 2.

Each of the 10 rescuers takes a 1-h shift.

Thus, each rescuer has a 1% chance of death because each would be in the tunnel one-tenth of the time, and one-tenth times 10% is 1%.

This scenario examined the *ex ante* fairness for the rescuers in doing their jobs, before the risk outcome (possible death of a rescuer) has the uncertainty resolved. Among respondents asked to indicate the fairer option, large majorities felt that Option 2, where each rescuer faced 1 h of risk, was fairer

(96% of 53 American adults, 96% of 51 young Chinese adults, and 82% of 49 middle-aged Chinese adults). For those who were asked which option would be chosen (not which is fairer), relatively large majorities chose Option 2 (83% of 53 Americans, 84% of 47 young Chinese adults, and 62% of 49 middle-aged Chinese adults).

For societal decision makers, it is often important to consider the *ex ante* risk to members of society, because society members may prefer a more equal distribution of *ex ante* risk, if feasible; see Keller *et al.* [29] for an example of a decision model that incorporates a preference for *ex ante* equity.

Miner Location Scenario

Now consider the “Miner Location” scenario from Keller and Sarin [28] with American respondents and by Bian and Keller [27] with Chinese respondents.

On an island within your jurisdiction, 100 miners are trapped, 50 in location A and 50 in location B. Two rescue options are possible.

Option 1.

Attempt to rescue all the miners in both locations.

The possible outcomes are

50% chance that none die (because the rescue operation is successful);

50% chance that all 100 die (because the rescue operation is not successful).

(Considered more fair by most Americans and Chinese, chosen as the action to take by most Americans and a weak majority of young Chinese adults)

Option 2.

Attempt to rescue only the miners in one location.

The possible outcomes are

50% chance that the 50 miners in location A live and the 50 miners in location B die because the rescue operation is sent to location A;

50% chance that the 50 miners in location B live and the 50 miners in location A die because the rescue operation is sent to location B.

(Chosen as the action to take by a weak majority of middle-aged Chinese)

In Option 1, the miners all experience the same common fate, since either all 100 would die or all would live, so this is an *ex post* equitable option, in the sense of Fishburn’s [35] common fate axiom. In the survey, a strong majority of American adults and a weak majority of young Chinese adults chose Option 1, where the miners all experience the same common fate. In contrast, a weak majority of middle-aged Chinese adults chose Option 2, which results in common fate inequity, but avoids the catastrophe of all 100 miners dying. A possible explanation for this difference in choices is that the traditional Chinese culture places more emphasis on protecting the group, as expressed in the cultural value of collectivism. (In contrast, the American culture places more emphasis on individualism.) Therefore, the middle-aged Chinese who chose Option 2 avoided the possible loss of the entire group.

For societal decision makers, it is sometimes important to consider the *ex post* risk to members of society; see Keller *et al.* [29] for an example of a decision model incorporating a preference for *ex post* equity. As illustrated in this common fate scenario, models may need to be flexible enough to be consistent with preference for equity or inequity, depending on specific contextual or cultural factors.

CONCLUSION

This article has provided a brief theoretical and empirical introduction to the examination of fairness and equity in societal decision analysis. For a more advanced discussion of “risk equity,” which considers risk in scenarios with probability distributions over health or safety outcomes, see Keller *et al.* [29].

In conclusion, societal decision makers need to consider the fairness of their allocations and their allocation process. In some situations, they may want to reason normatively about which fairness principles to follow. In others, they may wish to consult with stakeholders about perceptions of fairness or

gather experimental survey data to confirm what the affected population would prefer.

FAST AND FRUGAL HEURISTICS

SVEN BERTEL

ALEX KIRLIK

Human Factors Division and Beckman
Institute for Advanced Science and
Technology, University of Illinois at
Urbana-Champaign, Urbana, Illinois

Cognitive heuristics are fundamental to human judgment and decision making. Often described as rules of thumb that are used in lieu of optimal procedures (e.g., when resources are limited, or knowledge is incomplete), cognitive heuristics may also be understood as essential psychological mechanisms that guide information search and produce decisions by effectively and efficiently exploiting information structures in the environment. This article describes a selection of simple but powerful, task-specific, fast and frugal heuristics (FFHs) as suggested by Gigerenzer, Todd, and the ABC Research Group [1]. Underlying assumptions related to concepts of ecological rationality are presented, as are basic mechanisms of, and research into the validity of FFHs.

Heuristics as a term has been used to designate a number of radically different concepts across the ages and disciplines. The modern English term is ultimately derived from the Ancient Greek *εὑρίσκειν* (“to find”), perhaps more widely known by the exclamation generally attributed to Archimedes of Syracuse after realizing, upon stepping in his bath and inspecting the amount of water displaced in the act, the basic principle of buoyancy: *Eureka!* (“I found it!”).

HEURISTICS AS PROCEDURES FOR PROBLEM SOLVING

In early modern times [2], *heuristics* came to describe the study of procedures and techniques that lead to discovering solutions to previously unsolved problems and to scientific discovery in general [3]. Descartes’ *Discours de la méthode* can be seen as an early

work in this tradition with its reduction of difficult problems into as many parts as is feasible and necessary to recognize their individual truths directly by human intuition [4]. Heuristic procedures often comprise an element of induction: Gigerenzer and Brighton [5, p. 108] provide a good example of a distinction made by George Polya between heuristics on the one hand and analytical methods on the other: while “heuristics are indispensable for finding a proof, [...] analysis is required to check a proof’s validity”.

The original reading of heuristics is still to be found in the psychological (e.g., Gestalt) lingua of the first half of the twentieth century. For example, with regard to human problem solving, Duncker defined heuristic methods of thinking as general procedures for which an “insistent” analyses of the situation, especially the endeavor to vary appropriate elements meaningfully sub specie of the goal, must belong to the essential nature of a solution through thinking” [6, p. 20f]. It is in Herbert Simon’s work [7,8] that we find classic functional descriptions of human reliance on heuristics, for instance, with regard to problem solving, along with explanations of what causes this reliance: According to his view of the matter, people usually do not maximize (i.e., they do not search for a problem’s optimal solution); rather, they *satisfice* (i.e., look for a solution that is deemed good enough). This satisficing behavior is caused by, internal factors such as cognitive limitations, as well as by external factors, such as in the environment and the problem structure, which may, for example, induce prohibitively high computational (or other) costs for actually finding and verifying an optimal solution.

It is also in this original reading of the term that heuristics came to be used in other fields, including computing. In recursive algorithm design, divide-and-conquer algorithmic paradigms, which include many standard data sorting and search algorithms, follow a similar pattern: a computational problem is broken down recursively until the individual parts can be solved easily enough; the

partial solutions are then combined into a global solution for the problem as a whole. The fields of computing in general and of artificial intelligence in particular are shaped by searches for good heuristics, which make computational problems that often are NP-hard in their general form (e.g., the traveling salesman problem, chess, etc.) computationally tractable for some relevant practical contexts; for example, by reformulating the problem representation (such as by making it more specific) or by reformulating the processes that operate on this representation (e.g., by defining optimality criteria locally rather than globally).

HEURISTICS AS PROCEDURES RESULTING FROM TRADE-OFFS BETWEEN EFFORT AND ACCURACY

Goldstein and Gigerenzer [9] point us toward the eventual changes in the use of heuristics that occurred in the late twentieth century. Heuristic procedures were then often contrasted with optimal procedures, with the former being seen simply as the poor man's version of the latter. Heuristics had a place (only) when the corresponding optimal procedures were unavailable; for instance, because mental operations or computation for the optimal procedures were too costly or because they would involve too much or unavailable knowledge. In other words, heuristics in this second reading of the term constitute suboptimal rules (i.e., rules of thumb), in particular, rules that insure effective cognitive functioning in the presence of strong limitations to cognitive processing: "The common procedure [...] is to start with a method that is considered optimal, eliminate some aspects, steps, or calculations, and propose that the mind carries out this naive version." [9, p. 75].

This view assumes, as a corollary, that results produced by heuristics, while perhaps on acceptable levels, will generally be of a poorer quality than results of ideal procedures. Quality of results may thus be improved by allocating more processing resources, by using more information, or by allowing more time for the processing

[5]. While heuristics in the first sense of the term do not emphasize optimality (or, rather, suboptimality) as a defining criterion, the second reading does. Heuristics are (computationally) cheap versions of optimal procedures that produce results inferior to those of optimal procedures, and you would only want to use heuristics when a running of corresponding optimal procedures is not an option; for instance because of cognitive limitations. Using less effort than required for the optimal procedures comes at the price of reduced accuracy.

HEURISTICS AS FUNDAMENTAL PSYCHOLOGICAL MECHANISMS

Fast and frugal heuristics (FFH)s as proposed by Gigerenzer *et al.* [1–12] add yet a third reading to the term heuristics that combines elements of the first two readings and also adds additional aspects. It shares with the first reading that heuristics enable us, as humans, to make judgments, decisions, or solve difficult problems; it differs from it in that heuristics in the third sense are not detailed, compositional procedures that one follows as one follows a recipe during cooking, but rather are a collection of (mostly, very) simple rules that are followed largely implicitly or subconsciously in human decision making.

This third reading of heuristics shares with the second reading that both types of heuristics are relatively simple and that their executing requires comparably little cognitive and computational resources. However, the third reading differs from the second in that there is no need for a comparison with alternative optimal procedures, not even a need for the existence of such procedures, but that heuristics instead constitute a group of fundamental psychological mechanisms that guide information search and produce decisions by effectively and efficiently exploiting information structures in the environment. As we will see in the following, the readings also differ in their assessment of how beneficial more processing and more information are for the accuracy of results of the decisions that are taken.

FAST AND FRUGAL HEURISTICS AT FIRST GLANCE

Bishop [13, p. 202] sums up the two basic tenets of the research program on FFHs carried out by Gigerenzer *et al.* as follows: (i) humans “are naturally disposed to use simple reasoning rules,” and (ii) “these rules are about as reliable in the long run as ideal rules.” In more detail, FFHs are frequently characterized by several or all the following properties: (i) FFH are ecologically, but not logically, rational; (ii) they have evolved as fundamental psychological mechanisms effective in human and animal adaptive problem solving; (iii) they operate in fast, frugal, and simple ways; (iv) they are precise and transparent enough to serve as basis for computational, model-based descriptions of cognition; (v) they are generally psychologically plausible. We will look at each of these properties in turn, beginning with a comparative discussion of ecological rationality of heuristic procedures and “normative” rationality in ideal procedures.

HEURISTICS AS ADAPTIVE PROCEDURES FOR SUCCESSFUL BEHAVIOR IN AN ENVIRONMENT

What does it mean for a set of heuristics to be ecologically rational? Let us first consider some more general points. Basically, the question comes down to one of relative performance with regard to the conditions that are prevalent in the structure of the environment. On a general level, any natural perceptual or cognitive system on this planet has evolved given specific environmental conditions; the systems have adapted to these conditions to a degree where effective functioning depends on, and only makes sense, given the conditions’ presence.

Exploiting environmental conditions for the functioning of biological systems has clear procedural benefit (e.g., as it leads to a reduction of functional complexity). For example, Lockhead and Pomerantz [14] write on the interrelationship between structures in the world and perceptual functioning: “The significance of structure

for understanding perception resides in three tenets: first, that structure abounds in the physical world; second, that a perceptual system that knew about and capitalized on such structure would enjoy advantages in the speed and accuracy of perception; and third, that biological perceptual systems do exploit structure.” [15, p. 10]. It is important to keep in mind that such adaptation can occur on different levels (i.e., it is not limited to perception) and that it can be induced by different kinds of processes, including evolutionary, social, or individual (i.e., learning) ones. Many environmental properties seem to be fairly constant even when we consider them under evolutionarily relevant time spans. As a matter of fact, many environmental properties are so basic that their presence has become (or, always has been) necessary for biological life itself: a specific distribution of certain physical elements in the immediate vicinity (such as of gases in the atmosphere, for creatures such as humans), a gravitational pull of certain strength, regular daylight of certain wavelength distribution, and so on. When it comes to human and animal judgment and decision making, properties of such kind are perhaps not too often involved, at least, they were not under evolutionary terms as there is/were not much variation. (Or, if there were, there would not be anyone left to make a decision.) Many other equally relevant environmental properties, however, do require adaptive judgments and decisions on actions on behalf of the individual; these include, among others, the availability and distribution of environmental features such as food, water, or suitable mates within a specific area. There is little doubt that many of such (and other) judgments and decisions in animals and humans, which require adaptive problem solving, are made based on the outcomes of heuristic procedures and that at least some of these procedures are surprisingly simple [16]. Consider, for example, strategies that a peahen may employ for choosing a suitable mate. She may try to base her decision on all the information that is potentially available to her and act as close to an “ideal” procedure as possible (e.g., she could compare all

available peacocks on a number of features, then compute expected overall utility values for each peacock based on a weighing of individual features, and finally choose the one peacock with the highest score), or she may employ a much simpler procedure (i.e., a heuristic), perhaps one with just a single cue: inspect only a few candidates and pick the one with the highest number of eyes on his train. There is an evidence that peahens do, in fact, act upon the second, simpler strategy [17]. How should one evaluate such choice of strategy? If we follow the notion that heuristics (in the sense of the second reading of the term) are suboptimal procedures that evolved from necessary trade-offs with limited processing resources (e.g., possessed by our peahen) then one should assume that the more inclusive first mate selection strategy should lead to better choices of mates. If one follows the notion that heuristics (in the sense of the third reading of the term) are basically mechanisms which have evolved to work well (perhaps, even be optimal?) given a certain type of environment, then such an assumption does not need to hold. Similar issues of strategy evaluation can be raised for pretty much any heuristics-based decision or judgment. It seems that only a look at some actual performance data can clarify this matter, so let us now turn to performance results of a selected simple heuristic, before again addressing questions of ecological rationality.

THE LESS-IS-MORE EFFECT

Let us inspect one example among the FFHs that have been proposed so far. Goldstein and Gigerenzer [9] present an effect which, at least on a surface level, should appear most counterintuitive to the reader trained to trust that possessing and considering more relevant information in a decision process will mean an increase in the quality of obtained results. Countering that belief, Goldstein and Gigerenzer show that, in some situations, a little ignorance (i.e., less relevant knowledge for a decision or judgment) on a topic can in fact lead to taking better decisions than having more

knowledge. They present a study in which they asked groups of students from Germany and the United States to decide whether San Antonio or San Diego is, in fact, the larger city. While about two-thirds of the American students correctly named San Diego, all of the German students in the study produced the correct answer despite possessing much less knowledge about US cities than their American counterparts. How is this possible? Surely, more knowledge about the cities in this study (and about any relevant domain in general) should have resulted in more accurate judgments on the cities' relative size. This means that the American students should have outperformed the German group. Goldstein and Gigerenzer argue that employment of a powerful FFH, the recognition heuristic, causes the high performance levels of the German students. This heuristic can be summed up as follows: *If only one of two alternatives is recognized, infer that the recognized alternative has the higher value on the decision criterion.* Most German students in the study had recognized the name of San Diego but not that of San Antonio, and they had subsequently decided on the recognized city. Most American students in the study, however, were unable to employ this particular heuristic as they knew too much (i.e., they recognized the names of both cities). Goldstein and Gigerenzer refer to the effect as the less-is-more effect.

A similarly strong result of the recognition heuristic has been demonstrated by Borges *et al.* in the area of investing in the stock market [18]. A test of the recognition heuristic (i.e., buy only those stocks whose names are recognized) against a number of different investment strategies showed that the recognition heuristic in fact, outperformed the strategies during the 6-month period of the test. On a related note, performance in inference-making may even benefit from the systematic forgetting of knowledge [19].

Let us now step back from the individual studies and return our attention to the more general picture: When is the recognition heuristic ecologically rational; what is its accuracy? Surely, this particular heuristic cannot be always rational, or we should immediately act and close all schools and

libraries, as well as hide all books, so that we can all know less and become more accurate at making judgments and decisions. While a reproduction of the actual deduction of when a less-is-more effect will occur is beyond what can be shown in this article [9], the claim is that “any strategy for solving multiple-choice problems that follows the recognition heuristic will yield a less-is-more effect if the probability α of getting a correct answer merely on the basis of recognition is greater than the probability β of getting a correct answer using more information” [9, p. 79f]. The discovery of the less-is-more effect has been described as “one of the major discoveries of the last decades” [20]: “Contrary to the belief in a general accuracy-effort trade-off, less information and computation can actually lead to higher accuracy, and in these situations the mind does not need to make trade-offs. Here, a less-is-more effect holds” [5, p. 109].

A SECOND TAKE ON ECOLOGICAL RATIONALITY

It should have become clear by now that the reasons for the existence of the less-is-more effect exhibited by the recognition heuristic have to lie in how the heuristic manages to exploit certain properties of the information structure in the environment. In other words, the effect is context-dependent. Let us now look more closely at which environmental properties it actually depends upon.

Imagine trying to fit a function to a set of observed data samples. It has been known for some time that models (i.e., functions) that achieve good data fits on observed data samples do not necessarily result in equally good predictions of additional data [21]. On the one hand, the higher the degree of the polynomial used as model, the lower the error between the model and the observed data. On the other hand, the higher the degree of the polynomial, the greater the model’s flexibility and the greater its ability to not only pick up the underlying function that one intends to model but also the accidental variation in the data sample that is due to noise or statistical variance. If the model is very sensitive to

noise or variance, it easily overfits the data sample and is likely to predict poorly.

In order to better make the point of why simple heuristics can lead to more accurate results than more information-rich procedures, Gigerenzer and Brighton [5] suggest an error function of the kinds common in machine learning, in which the total prediction error equals the sum of three terms: the squared bias, the variance, and the noise. Bias is then defined as the difference between the “true” function underlying the data and a mean function produced from the data sample through some assumed induction process. If both functions are identical, there is no bias. The variance term simply adds a measure of how susceptible the induction process of the mean function is to patterns specific to the individual data samples; Gigerenzer and Brighton define it as the sum squared difference between the functions induced from individual data samples and the mean function. Assuming that noise is an invariant property of the environment, or that it invariably comes with taking data samples from it, low prediction errors can only be ensured by keeping both bias and variance at bay. On the basis of their error function, Gigerenzer and Brighton make a two-part argument. First, they relate the goal of attaining low prediction errors to the bias-variance dilemma [22]: for a low bias on a broad predictor, a model must accommodate various patterns. This, however, likely comes with greater flexibility, which in turn leads to greater accommodation of accidental data patterns and ultimately, to greater variance and a higher total prediction error. The way to keep variance down, on the other hand, is to reduce the broadness of the model, which in turn leads to a likely increase in bias and again, a higher prediction error. With reference to Geman *et al.* [22], Gigerenzer and Brighton conclude that it is due to this dilemma, that “‘general purpose’ models tend to be poor predictors of the future when data are sparse” [5, p. 120]. Second, they bring in findings indicating that human performance in generalizing from only few observations is often remarkably accurate [23]. Both points can be consoled when one, first, considers heuristics in human cognition to be specialized

rather than broad in order to keep variance (and, thus, total prediction error) down and, second, when one considers a whole set of biased, specialized heuristics (an adaptive toolbox, in FFH terms) to account for accurate human performance in judgment and decision making across a broad spectrum of contexts.

Gigerenzer and Brighton argue that the relatively high predictive accuracy of heuristics is often simply due to their ability to control variance better than more flexible models can. They note that “the variance component of error is always an interaction between characteristics of the inference strategy, the structure of the environment, and the number of observations available. This is why the performance of heuristics in an environment is not reflected by a single number such as predictive accuracy, but by a learning curve revealing how bias and variance change as more observations become available.” [5, p. 120]. A use of heuristics can lead to more accurate performance than a use of strategies with more information, more computation, or more time “not because the world is similarly simple,” but instead “by betting on lower variance, not lower bias” [5, p. 124]. As a consequence, simple heuristics fare particularly well under those conditions, under which variance is the dominant source of prediction error. Naturally, these include those under which observations are sparse or noise is high.

AN ADAPTIVE TOOLBOX OF FAST AND FRUGAL HEURISTICS

The research program on FFHs has so far included a number of heuristics of various sorts. One of the program’s most recent publications [5] lists 10 well-studied examples, together with criteria of ecological validities and related surprising findings; for reasons of space, we will only name two more here, in addition to the recognition heuristics already discussed above. The fluency heuristic (if both alternatives are recognized, but at different speeds, choose the faster one) shows a less-is-more effect comparable to that of the recognition heuristics: systematic forgetting

can lead to more accurate predictions [19]. The imitate-the-majority heuristic is ecologically rational in stable environments or when search for information is very costly: consider the majority of people in your peer group and imitate their behavior.

OTHER PROPERTIES OF FAST AND FRUGAL HEURISTICS
